When all was over we took account of stock. In order to be ready for all emergencies we had a can of oxygen standing in the room, strychnine and whiskey standing on the table, and a loaded hypodermic waiting. When the child was well there were wanting four strychnine tablets—one-sixtieth grain each, and one drachm of whiskey. These were all the drugs used.

For the characteristic toxemic condition of pneumonia in infants and children, my experience leads me to set forth again certain conclusions recorded in the *Medical News*, April 30, 1904, as follows:

How to cure a baby with bronchopneumonia.—

1. Castor oil to clear the field of operation. It is the first aid to the injured.

2. Fresh air, cool and flowing. It reddens the blood, stimulates the heart, improves digestion, quiets restlessness, aids against toxemia. Regulate the temperature of the air in the room inversely to that of the child. The patient's feet must always be warm, and the head cool.

3. Water, plenty, inside and outside. Temperature of the water as indicated by child's temperature.

4. Quiet and rest. Tranquilizing influences about patient. Undisturbed sleep.

5. Correct the feedings to prevent fermentation

and the formation of gas in the abdomen. If there is need, give high hot salines.

6. Antipyretic: Water; no coal-tar products.

7. Heart stimulants: Fresh air, hot foot baths, relieving tympanites and crowding. Hot foot baths and hot salines can be given in a cold room; both can be given under the bedclothes.

8. Drugs: Whiskey and strychnine. These are the first drugs mentioned, unless that household remedy, castor oil, be included. Promote general comfort in every rational way.

How to Kill a Baby with Pneumonia.—Crib in far corner of room with canopy over it. Steam kettle; gas stove (leaky tubing); room at 80° F. Many gas jets burning. Friends in the room, also the pug dog. Chest tightly enveloped in waistcoat poultice. If child's temperature is 105° F. make a poultice thick, hot, and tight. Blanket the windows, shut the doors. If these do not do it, give coal-tar antipyretics and wait.

57 East Seventy-ninth Street.

PREVENTIVE MEDICINE: A STUDY IN EDUCATION*

By LAWRENCE T. ROYSTER, M.D.,
Norfolk, Va.
Member of the Norfolk School Board.

Mr. President, Members of the Commission, Ladies and Gentlemen:

I feel that I am especially honored in having the privilege of speaking before such an illustrious and important body as the Cooperative Education Commission of Virginia. The subject which I introduce for your consideration this morning seems to my mind of signal consequence; for what could be more important than teaching students the proper care of their health, since we well know that we cannot have a sound mind without a sound body.

A somewhat lengthy introduction to a very brief discussion of the matter is necessary to a proper understanding of the intents and scope of the paper. If medicine and the physician appear to have been given an undue prominence I ask your indulgence, reminding you that this is only as the matter appears through a pair of medical spectacles.

Preventive Medicine (Prophylaxis, Hygiene) is a term which may be used in either of two senses; the difference, however, being one of application. The prevention of infection, for example, by the proper application of the rules of asepsis—Prophylaxis; or the prevention of the spread of communicable diseases in communities, through such measures as quarantine, preventive inoculation (*e.g.* vaccination), etc.,—Hygiene. In both of these applications of the term the same principle obtains. It is in the larger and broader sense—its application to Public Health—that I use the term Preventive Medicine.

When Moses had led the Children of Israel out of Egyptian bondage across the Red Sea into the Wilderness, he laid down certain laws concerning personal and public cleanliness, through a due observance of which the camp was to be purified and a hygienic condition maintained.

These laws applied to the isolation of the sick of certain (contagious) diseases for periods of time varying with the disease; the quarantine and subsequent disinfection of infected houses with, in some instances, even a scraping of the plaster from the walls; the removal of refuse out of the camp or city limits; and the burial of excreta. These laws were so rigidly enforced that the penalty in extreme cases was ostracism or even death.

The method of executing these laws was of course crude, and some of the laws themselves showed a generous admixture of superstition, yet the principle involved is identical with the most improved hygiene of modern times, and when we consider the primitive nature and low grade of development of the people of that time, we are led almost irresistibly to see the influence of a supreme being, not even losing sight of the education of Moses, who was "a proficient in all the learning and arts of the most civilized nation of the earth"—the Egyptians.

We read also that "Empedocles of Agrigentum, one of the most famous of ancient philosophers and physicians, finding that pestilential fevers periodically ravaged his native city, and observing that their appearance coincided with the return of the sirocco, which blows in Sicily on its western side, advised closing by a wall, as by a dam, the narrow gorge from which the wind blew on Agrigentum. His advice was followed, and his city was made free from the pestilence."

"Again the inhabitants of Selinus were ravaged by epidemic disease; a sluggish stream filled the city with stagnant water from which mephitic vapors arose. Empedocles caused two small rivulets to be conducted into it, which made its current more rapid; the noxious vapors dispersed, and the scourge subsided."

It is beyond question that these are two instances of an effort to rid a locality of disease-bearing mosquitos or other insects.

Passing over many ancient and interesting examples of Preventive Medicine, we come to more recent events along this line of which I will mention but two before considering matters of vital interest to us at the present time. One, the discovery by Jenner of vaccination whereby we are enabled to combat the severest epidemic of smallpox; by its proper application the ravages of this disease would probably be stopped entirely. The other, a well directed effort to prevent the spread of venereal disease through a control of prostitution by means of license and inspection, which has been done principally in Paris and Vienna. Good results were hoped for from this effort, but experience has shown that it has failed of its purpose.

But whereas apparent failure has been met with in many instances by those endeavoring to work a benefit to mankind, numerous successes have been scored, and of these and the further possibilities in the direction of Public Health, I will now treat.

Laws have been made by most if not all municipalities of this country concerning proper systems of sewerage and drainage; sanitary plumbing has been introduced and is required almost universally; boards of health have been created and invested with powers looking to a control of infectious diseases by isolation, quarantine, vaccination, etc., the filling up of stagnant pools and unsanitary cisterns, and the inspection and disinfection of private residences and public buildings.

The water supplies of our large centres of population are under the supervision of such boards, who by the aid of well-equipped bacteriological and chemical laboratories, and approved filters, are enabled to keep the water free from contamination, and thereby eliminate a large element of danger of the spread of at least one disease—typhoid fever.

The public is at last becoming aware that tuberculosis is a communicable disease with the result that popular crusades against the "white plague"

*Read in part before the Cooperative Education Commission of Virginia, at its Norfolk Session, December 6 and 7, 1904.

For obvious reasons, in the delivery of this address, some of the paragraphs were either changed to suit the occasion or omitted altogether.

are becoming the order of the day, and it is hoped that by this means eminent success may be achieved in reducing the present fearful mortality from this disease.

Many examples could be cited of what has already been done towards securing a healthy state of affairs in many sections of our country, but I hasten to a consideration of what is yet to be done, and may be accomplished through concerted action and harmonious cooperation between physicians (both individually and collectively) and the public, through its representatives in our legislative bodies.

Laws must be enacted and together with those already in existence enforced. Concerning our health boards, nothing definite will be accomplished so long as competent men are turned out with each change of administration, and incompetent ones substituted. Under this system, even if good men are appointed, they have to spend most of their term of office learning what their predecessor knew, only to be themselves replaced when they have acquired a sufficient familiarity with the duties of their office to make them useful to the community.

The various positions held by medical men should pay a salary sufficiently large to justify the holders in giving up their whole time to their official duties. This could be done, certainly in the smaller cities, by combining several positions. Nothing is to be deplored more than the general tendency to fill such positions as sanitary inspector and the like from the rank of "ward heelers" and superannuated politicians, as a reward for their efforts in the political arena, without regard to their fitness for the important positions they are to occupy. Only active, intelligent, and conscientious men who have the interest of the community and the welfare of their fellowman at heart should be chosen for such positions, and when found to be efficient and capable should hold office indefinitely.

Ordinances prohibiting expectorating on sidewalks and the floors of public buildings and conveyances, should be rigidly enforced. This measure alone would materially diminish the spread of tuberculosis. Food inspection should receive special attention, preventing the sale of unsound meat and infected and unclean milk. The latter is particularly important because of the large number of infants who are wholly dependent on this article for sustenance. The inspectors should see that the cans, hands of the milkers, udders of the cows, and in fact everything pertaining to the handling of this article of food is scrupulously clean. The milk should be put into clean bottles, sealed at the dairy, and delivered to the consumer at a temperature not exceeding 50° F. Such procedures as this would largely prevent the spread of various bowel disturbances and typhoid fever, and reduce to a minimum the mortality form of the summer diarrheas of infants.

Great benefit has already been derived from vaccination, but before this measure can be said to have fulfilled its mission, its practice must be made compulsory by rigidly enforced laws. The indiscriminate sale of poisons, especially opium and its derivatives and cocaine, without a physician's prescription should be stopped at all hazards. Laws on this subject have been made in many States, unfortunately only to be totally disregarded even in many instances by supposed reputable druggists, with the consequence that our towns contain vast numbers of "drug fiends," and the columns of our daily papers tell of the poor unfortunates who are found dead with the usual laudanum or carbolic-acid bottle lying near.

One of the greatest curses in our land to-day is charlatanism, carried on through the quack advertisements of "specialists" in "diseases and weakness of men" or "female irregularities." The former having for their victims either men worn out from excess, or young men who from ignorance do not consult the family physician, fearing that their parents might know of their condition, and so seek aid from these base and unscrupulous charlatans who give their advice under the protection of "plain and sealed envelopes." The latter prey upon a still more unfortunate class, viz., young girls who have perhaps "loved not wisely but too well," and dreading parental and public censure are ashamed to seek protection in properly conducted institutions; and also, and I blush to think of those married women who, not caring to give up their worldly pleasure to assume the honorable rôle of motherhood and fulfill their mission in life and do their duty in the home, preventive measures having failed, are pregnant and seek relief through these "specialists" and their remedies, both of which are destructive to body and soul alike. And yet our administrations not only permit these things to flourish, but often add their stamp of approval by granting a license, and the public looks on in smiling approval.

Nothing demands the attention of our legislators more than the patent medicine "craze," for such it seems at present to be. Many of these articles contain noxious and deleterious ingredients, whiskey, opium, cocaine, and the like, which undermine the constitution; others are harmless in that they contain nothing that is positively detrimental, but are injurious in that they cause suffering humanity, through a reliance on the false claims for their virtues in cleverly written circulars and advertisements, to delay seeking advice from intelligent and reputable physicians until they are beyond the reach of legitimate medical aid, which, if rendered sufficiently early, might have saved them from much suffering or even perhaps an untimely end. Certainly the vast majority of these nostrums are vaunted cure-alls to extort money from an ignorant, trusting, and gullible public.

If the sale of these articles cannot be stopped, we can certainly emulate the example of our German friends and require every bottle or box to bear in plain print the exact formula of its contents, attested to before some person whose business it is to make such analyses as may be required.

The various "pathies," "cults," and "sciences" which either deny the existence of disease or handle it on absolutely unscientific principles, and thereby menace the health of a community, should receive careful consideration from our legislative bodies, and should be made to conform to rules and regulations of the boards of health. These are too numerous to mention separately, but the most potent is Christian Science, that aggregation of ancient, arrant, and palpably pagan principles, reincarnated in a cunningly devised modern Christian (?) charlatanism, which, exercising authority over its followers through the strongest of all human instincts—the religious, holds in contempt all known laws of physiology, pathology, and hygiene, and hurls defiance in the face of our courts of law and justice.

In a general, superficial, and desultory way I have outlined the more important instances in which legislation would materially aid in maintaining a healthy condition of our centers of population; but the great difficulty in the way of attaining even an approximate degree of ideality in this direction is in getting our lawmakers sufficiently interested to see the vast importance of such measures. This difficulty—and only those who have tried to secure

the passage of health laws know how great the difficulty really is—arises from two powerful causes, the one ignorance (of the laws of health) and the other political graft, and the public, of whom these legislators are but the representatives, are themselves too ignorant to demand a better state of affairs. Naturally the question arises: How are these difficulties to be overcome, the health conditions of our country improved, and a sanitary state of affairs maintained?

The answer to this momentous question as it suggests itself to my mind, is (1) by sending educated and conscientious men to our town councils and general assemblies, and (2) by educating the public in the laws of health so they will recognize the cause of unhealthy conditions and know the proper methods of overcoming them. By attending to the second part of this answer the first will follow as a natural consequence.

It has been said by one of England's foremost scientific men—Forbes Winslow—that "it is an admitted fact that ignorance prevails to an alarming extent, and that its only corrective is education." Hence it will be seen that in the one word, Education, lies the secret of performing what is apparently a gigantic and stupendous undertaking. A plea then for the education of the people along lines of personal and public cleanliness and health, is my apology for presenting this article for the consideration, and may I hope, approval of a generous public.

Two general lines suggest themselves through which we may attain the object of our endeavors. First, the public can be taught much that relates to the care of individual health, that of the household, and finally that of the community in which they live. Physicians whose mission, it must be remembered, is just as great in preventing as in curing disease must be ever mindful of their duty in instructing those among whom they move concerning the care of the household in health as well as in sickness, how to keep sinks, cesspools, toilets, drains, and the premises generally in a healthy condition; and in short what constitutes a sanitary and what an unsanitary state of affairs, teaching them to maintain the one and prevent the other.

The various societies and associations of medical men, while assembled for the purpose of an exchange of ideas among themselves and of promoting scientific research, enabling them to alleviate the suffering of afflicted humanity, should not lose sight of their responsibility to the public in disseminating such knowledge as will be instrumental in securing a cooperation from the people which is essential to the success of the undertaking under consideration. This can be done by publishing such information as pertains to the public good; this information appearing as published extracts from the proceedings of the meetings.

Popular lectures have done much towards educating the public in medical subjects and can be made one of the most fruitful sources of benefit to the masses of the people. Likewise articles by well-informed men, touching on the hygiene of the person, household, and community, could appear in our magazines and daily papers, written not in technical phrases but in such language as could be understood by people of limited education and even moderate degrees of intelligence.

Concerning our daily newspapers, let such news as will be of service in improving the mind and uplifting humanity take the place of attractively-written articles with glowing headlines that tell of crime, degradation, and misery, which shock the sensibilities of adults and poison the minds of youths.

Second, and I come to the climax of the subject, the education of the youth of our land. Truly "the child is father to the man." The boy of to-day is the man of the future. The girl who to-day is playing with her dolls and toys in a miniature household, will in the next generation be laying a foundation of principle (good or bad) in the minds of her real family whose influence may be felt throughout the universe. How vastly important is it, then, that these young people, many of whom are destined to be the rulers of men, should be taught how to care first for their own health, and second for that of the community.

The first place where a child should receive this necessary instruction is in the home. To this end parents must be instructed how in turn to teach their children so that their first impressions of life, which are the most lasting, may be the correct ones; and as the mother teaches the child at her knee of the Creator and its duty to him, let her also teach it cleanliness (both personal and public) which is next to godliness.

The second place for this instruction is in the schoolroom. In the introduction of the study of hygiene, properly taught, into our school systems, lies, I believe, the keynote of success in securing and maintaining a sanitary condition of our centers of population. This branch of study must be taught thoroughly by competent teachers and might with advantage be supplemented by lectures by medical men; these lectures should be considered a part of the regular course and form a part of the subject matter for examination.

The scholars should be taught what disease is as opposed to health, its causes and results, how it is spread by such means as infected water and food, particularly milk, unclean utensils in the kitchen, and, not the least important, that special abomination, the public drinking cup; what constitutes a sanitary and what an unsanitary condition of the home, school, public building, or municipality; together with the means to be employed in correcting existing evils and preventing the spread of disease, through individual effort as well as legislative cooperation.

All of these things should be taught in our schools as thoroughly as are grammar and arithmetic, so that when these children grow up and become the men and women of the future, and especially our law makers, these first principles, which will have then become an integral part of a "national conscience," will outweigh all others and cause laws to be made that will bring about a universally sanitary state of affairs, and when this has been done, to be so enforced that such a condition can be maintained.

It is perhaps very noticeable that up to this time nothing has been suggested concerning the prevention of the spread of venereal disease. I have hesitated because I hardly knew what to suggest on a subject which has had so much thought given it and so many efforts made in its behalf, all apparently but to fail. Prostitution exists, has existed from time immemorial, and will exist so long as there are sexes; and so long as there are prostitutes there will be venereal disease. What, then, can be done to check its spread? License and inspection have failed signally, and even if they were effectual in the case of professional prostitutes, we would still have the vast army of clandestine prostitutes, who I sometimes think are a greater source of danger than the professionals.

There are two measures, however, which, if properly carried out, would materially diminish the spread of this evil. The first is circumcision. In regard to this procedure, I will simply say that its abolition (from a hygienic standpoint) is the only

retrograde step that I know of for which Christianity is responsible. Its practice should be universal.

The second is the same remedy that has been offered for the correction of all the other evils—namely, education. Teach the youth what venereal disease means, its nature, effects on the system, and ultimate results, how it is contracted and how avoided. There is no subject on which the public as a whole is more ignorant than that of venereal disease. They should know all about it, since nothing is more important. They have kept themselves or been kept too long in darkness concerning it. Now let there be light.

What has been said on all the phases of this great subject may seem a hard problem, and a state of ideality difficult of accomplishment may have been pictured, but *"Nil tam difficile, quin diligentia vincat."*

If our physicians, medical bodies and school boards alone will work together with untiring efforts much can be done. It may require a long time, perhaps as long as two generations, to bring about a condition even approximately perfect, but such a condition can be brought about by keeping at it, remembering that *"Gutta cavat lapidem, non vi sed saepe cadendo."*

Kala-Azar, or Tropical Splenomegaly.—Guy R. Ruata defines this affection as an infectious disease running a subacute or chronic course, nearly always fatal, characterized by fever of an intermittent or remittent type, anemia, wasting, enlargement of the spleen and liver, and not infrequently hyperpigmentation of the skin. This disease is met with in many parts of India, South China, and various tropical countries. It was at one time considered peculiar to the Province of Assam. It prevails in Assam during the rainy season, from April to September. Infection proceeds along the lines of communication. Isolated villages, although situated in the center of a region where an epidemic of this disease is raging, may not be affected. Kala-azar attacks both old and young, with no distinction of sex. Opium smokers do not seem so subject to attacks as do other members of the community. There are two clinical types of this affection: Subacute and chronic. The subacute form is characterized by decided symptoms. The fever is of a severe remitting type, marked anemia develops, and later cachexia. Rigors usher in the attack, after which the temperature rises and profuse sweating takes place. The spleen and liver enlarge and death supervenes in a few months from acute or subacute enterocolitis, pneumonia, or thrombosis of a cerebral vessel. The symptoms in the chronic form are less severe. Edema about the feet and ankles develops in the course of time, and fluid is effused into the serum cavities and into the subcutaneous tissues of the face. There are, besides these symptoms, rheumatic pains in the joints and muscles, frontal headache and neuralgia, hemorrhage from the gums and intestines and loss of hair. The skin becomes pigmented; this may be general or limited to definite areas. Emaciation progresses, accompanied by the loss of muscular energy, and drowsiness. The abdomen is swollen and puffy, due to the enlargement of the liver and spleen, and to the ascites. The arterial ocular circulation is deficient. Respiration is quickened. Sexual power is paralyzed. The disease was first described by Clarke in 1882. It was called "black fever," from the cutaneous pigmentation. The writer, in studying blood slides from a case of this disease, observed Leishman-Donovan bodies. These were never found in the peripheral blood. The writer gives a table showing the results of a blood examination made in the laboratory of the London School of Tropical Medicine, as well as Marchand and Ledingham's description of the parasite found in the spleen, liver, and bone-marrow. According to these observers, these bodies, under high power, were generally distinctly ring-shaped, with a clear center.—*Journal of Tropical Medicine.*

A Large Fibrosarcoma Treated by Röntgen Radiation.—Clarence Edward Skinner, after giving the details of this case, briefly summarizes it: The patient, a woman 34 years of age, was suffering from an abdominal tumor, the nature of which was a spindle-celled sarcoma. The growth measured ten inches in the horizontal from-side-to-side, eight inches in the vertical, and five inches in the antero-posterior diameters. It was inoperable, and had resisted every measure applied for its relief, and was rapidly developing lethal symptoms in the patient. It was entirely removed and the patient was restored to a condition of unimpaired usefulness and apparently perfect health by 136 applications of *x*-rays of high penetration from a tube excited by a static machine, the treatment having extended over a period of 849 days, being an average of one application every 6.2 days. The writer concludes that Röntgen radiation sometimes brings about the entire disappearance of large, deeply seated, malignant neoplasms, which have been proven to be hopelessly lethal in their tendencies under any other treatment, and simultaneously restores the patient to apparently perfect health. The lack of satisfactory influence which attends its employment in so many cases is not due to weakness inherent in the remedy itself, or to mere thickness of the tissues intervening between the pathological focus and the source of rays, but to some at present undetermined factors which remain to be identified, and which it seems justifiable to hope may sometime be eliminated. There is probably a direct and intimate connection between systemic toxemia and the disappearance of malignant growths under Röntgen radiation. The writer advocates persistence in the application of the Röntgen rays to a malignant growth of the same class as the one here reported, as long as the patient's condition will permit, even if no benefit is observable. In this case no material effect upon the tumor was demonstrable until after the radiations had been systematically and regularly carried out for six months. The writer believes that the difference between the rays derived from a tube excited by a static machine and those derived from a coil-excited tube will sometimes constitute the difference between success and failure in the treatment of deeply seated malignant processes. The patient was first brought to the writer in January, 1902, so that the question of recurrence still remains to be eliminated. However, even if the growth should recur, the patient who was doomed to death two years ago has for two full years been restored to a condition of unimpaired usefulness and comfort.—*Archives of Electrology and Radiology.*

Aids to Diagnosis in Renal Disease.—R. Steer-Bowker gives the following summary of his paper: In most cases, after studying the physical signs and symptoms, and having an *x*-ray photograph taken, it will be necessary only to segregate the urine with Luys' segregater, and then have an ordinary chemical and microscopic examination of the urine made. But in a doubtful case, where it is essential before operating that one should know whether the least affected kidney or other kidney has sufficient functional activity to carry on life, if it should be advisable to remove the one operated upon, then the urine should be segregated and tested by the "freezing point" or "Wright's test," and this evidence should be corroborated by the indigo-carmine test. By the use of these combined tests, and the simple form of segregation, the cystoscope is not required at all in renal diseases (unless there is some special indication for its use), time is saved, there is less danger of infecting a healthy bladder, the patient is saved some pain, and a deal of inconvenience. The cystoscope, then, can be relegated to its proper sphere of usefulness—examination of diseased conditions of the bladder itself.—*Australasian Medical Gazette.*

MEDICAL RECORD.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 18, 1905.

DIET IN PULMONARY TUBERCULOSIS.

THE main features in the successful treatment of pulmonary tuberculosis are fresh air and diet. Drugs have been relegated to the background. Perhaps by some enthusiasts the fresh air treatment has been carried to the extreme, such as recommending the heroic remedy of sleeping out of doors in every kind of weather, yet on the whole the principle of fresh air treatment of consumption is the only rational one. Opinions diverge more widely as to diet in pulmonary tuberculosis. Upon the quality and description of food there is a general agreement, but upon the important point of quality the wise men of the medical profession are not of one mind. Some believe in stuffing consumptives, while others think that no more food, as a rule, should be given than can presumably be properly digested.

The *Practitioner* for January, 1905, contains a series of three articles written by experienced English physicians, treating of the question of diet in pulmonary tuberculosis. The first of these, by Dr. R. W. Philip, considers the subject of zomotherapy in pulmonary tuberculosis. Zomotherapy has been defined by Professor Richet as the systematic, continued exhibition of raw meat in the treatment of the disease. Hericourt and Richet were the first to place this method on a scientific basis, and demonstrated by means of experiments with dogs inoculated artificially with tuberculosis, that raw meat was a most beneficial and remedial diet. Observations made upon human beings suffering from consumption would seem strongly to confirm the result of these experiments. The raw meat is administered in various forms, the essential point being that it must be fresh and freshly prepared before use. Philip supplements this dietary with raw eggs. The writer states that patients quickly become accustomed to raw meat as a food and soon learn to devour it with avidity. His conclusions with regard to the efficacy of this diet are in part as follows. 1. General aspect—The patient's color quickly improves. The pale, anemic look disappears. The tissues gradually—often rapidly—assume a firm, vigorous character. 2. Weight.—It is pointed out that increase in weight is no sure criterion of a patient's improvement. On a raw meat diet, the weight generally increases—an increase which is accompanied by firmness of tissue. 3. A prominent feature of treatment by zomotherapy is a remarkable increase of muscularity, with a correspondingly more active sense of well-being. 4. Circulation—The effect of the régime on the circulation is rapid and strikingly beneficial, one of the best indications that the treatment is proving effectual. 5. Temperature.—The temperature tends to improve. 6. Gastrointestinal functions.—The functions of stomach and bowel are rendered easier and more effective. Gastric uneasiness, pain, dyspeptic phenomena, and flatulence tend to lessen. Intestinal metabolism is rendered easier and more complete, as may be judged by the improved character of the stools. 7. Blood.—The blood presents a rapid increase in hemoglobin and Dr. Philip states that in no instances has he seen hemoptysis follow the institution of the method. 8. Local Lesions.—Local lesions are conspicuously benefited by the treatment. It is pointed out that the only disadvantages which have been urged against the method are: (1) The natural distaste which many persons have to such raw products; and (2) the possibility of the introducduction of intestinal parasites along with the raw meat. The writer is of the opinion that the latter danger is not a likely one if reasonable care be taken in the selection of meat, and even if a parasite be so introduced the actual harm to the patient is infinitesimal compared with the risk involved in the presence of the disease. The other objection is hardly worth considering, as not only does repugnance to raw meat quickly disappear, but is often transformed in a veritable like for this kind of diet.

The next article is by Dr. F. W. Burton-Fanning of Norwich, England. He is not an advocate of over-feeding in consumption, and says that "apart from the risk of over-straining the organs of digestion, the general health may suffer in consequence of too great addition to the body weight. The cardiovascular balance becomes deranged and the already feeble heart is unable to perform the extra work necessitated by the more ponderous frame." Dr. Fanning does not believe that full feeding has any special influence upon the reduction of fever, but thinks that air and rest are the most effective agents to bring down temperature. The greater part of the article is taken up with a consideration of dietary tables, a matter which has been so fully dealt with in the past few years that it would be superfluous to quote from them here. The writer holds that milk is the sheet-anchor in the treatment of pulmonary tuberculosis, and that it is by varying the quality of milk that we can most readily affect the ordinary patient's weight.

The last article of the series is from the pen of Dr. Arthur Latham, who is one of the most commonsense and practical authorities and writers upon consumption living. Considering the question of diet in pulmonary tuberculosis, he divides consumptives into two broad classes: (1) Those who have sound digestion and who are able to take exercise; and (2) those who are suffering from high fever or any disorder of digestion. With regard to the first class, Dr. Latham says: "Patients who come under the first heading may be given the ordinary diet of health, together with an extra quantity of fat, and two or three pints of milk daily. If the weight is much below the normal, the total amount of food given must be increased to what it should be if the weight were normal. If the patient's weight is normal, it is a mistake to press unduly the amount of food, as this sometimes leads to a disastrous interference with the physiological balance of the cardio-respiratory functions and body weight. Dr. Latham is of the opinion that milk is the most perfect food for a consumptive, but that it should not be given as his sole diet. With regard to patients who are

suffering from high fever, anorexia, or disordered digestion, the question of diet may be a formidable one. In such instances, however, the writer states that, whenever it is possible, cases of febrile tuberculosis should be treated by means of an ordinary diet. When this cannot be done, our aim must then be to supply, in the first place, sufficient nourishment in a suitable form to keep the disease in check; and secondly to place the patient on a solid diet at the earliest possible moment. In cases of febrile tuberculosis in which solid food is not retained, milk should be the staple diet, and at least four pints of it should be given. By far the most interesting part of Dr. Latham's article is the expression of his views as to the value of alcohol in pulmonary tuberculosis. He thinks that in those cases in which the digestion is good, the temperature is normal, and exercise is possible, there is no necessity to give alcohol, although small quantities in many instances are of undoubted benefit, but experience has shown that alcohol is of the greatest possible service when fever is present. It spares the body proteid, stimulates the appetite, and, in small doses, hastens gastric digestion. It facilitates the absorption of fat, and tends slightly to lower the body temperature. In addition, it stimulates the heart and the central nervous system, and favorably affects the night-sweats and the sleeplessness. The writer lays stress on the point that the alcohol should be pure and of best quality. In febrile cases red wine is especially useful. It may be given also with good effect in certain cases of tuberculous diarrhea. Referring to the amount of alcohol to be given, the writer states that while this must depend upon the individual case, nothing but good results from the administration of large quantities when fever is present, so long as the pulse is becoming slower, the appetite better, the skin and tongue moister, and the patient quieter. Careful examination of each individual case will show whether this food is overstepping physiological limits, and so causing pathological effects or intoxication.

The three articles in the *Practitioner* contain instructive matter, for although old ground has been necessarily gone over, yet the question of diet in pulmonary tuberculosis is well presented. The salient features of these articles would appear to be that zomotherapy is beneficial in the treatment of consumption, that milk is the most important article of diet, and that the use of alcohol is indicated in very many cases of pulmonary tuberculosis, and almost always when fever is present. Perhaps the trend of present-day treatment of consumption is against the use of alcohol, and especially in large quantities, even if fever is present. It is probable that the wave of temperance which has been sweeping through the world during the past few years, and which has been rightly helped along by scientific and medical men, has in the case of the use of alcohol in disease swung the pendulum of professional opinion too far. At any rate, it is refreshing to have the views of a well-known authority, as is Dr. Latham, who has the courage of his convictions and states the same in plain, unvarnished language.

Hospital Ships are to be exempted from the payment of port dues during the course of any future war, according to an agreement of the powers.

PROTECTIVE INOCULATION AGAINST ASIATIC CHOLERA.

The Bureau of Government Laboratories has just published Biological Laboratory Bulletin No. 16, by Dr. Richard P. Strong, treating of protective inoculation against Asiatic cholera. The experimental study described by Dr. Strong was based upon experimental work for the greater part performed during the spring of 1903 in the Institut für Infektionskrankheiten of Berlin.

The Philippine Islands have recently afforded excellent opportunity for studying Asiatic cholera, owing to the severe epidemic which has prevailed. The history of cholera in a tropical country has demonstrated the fact that it is impossible to eradicate or even satisfactorily control—according to Dr. Strong—the disease by ordinary hygienic methods—that is, by measures solely directed towards the purification of the food and water supply of infected districts. It was shown by studies made in the Manila laboratory, during the period of the most widespread infection, that in Manila at least the disease was not usually transmitted directly by water, but probably more often by food infection. Preliminary trials with Haffkine's method of protective inoculation showed the impracticability of using it in the Philippines. Consequently the experimental study now described by Dr. Strong was undertaken in the Biological Laboratory in Manila, with the view of obtaining some practicable and efficacious form of protective inoculation against the disease.

The account given in Bulletin 16 is an exhaustive one, occupying 46 pages, with numerous tables, and is far too long to review in detail here. It may be said, however, that the result of the investigation seems to have been on the whole satisfactory.

The following are the conclusions arrived at: 1. By the autolytic digestion of carefully killed cholera spirilla in an aqueous fluid the receptors become separated from the bacterial cells and may be filtered off in solution. 2. The injection of these free receptors into both man and animals furnishes a means of producing high bactericidal and agglutinative blood sera. The antitoxic value of these sera is, however, moderate. 3. The subcutaneous infection into man of such free receptors is a process which is not only free from any danger, but one which produces practically no local disturbance and only a slight general reaction. 4. Hence the method is a practicable one for producing a cholera serum in man. 5. It is highly desirable that the cholera prophylactic be given a thorough, practical test. 6. It would appear hopeful that by the application to the pest bacillus of a slight modification of this method a more satisfactory prophylactic against bubonic plague could be obtained.

A thorough, practical demonstration of the method described above will be necessary before any definite statement can be made as to its immunizing properties. Owing to the absence of cholera on a wide scale in the Philippines at the present time, it has been impossible to give the serum such a test. Arguing from the numerous statistics of Haffkine in India, and from the more recent work of Murata in Japan, that simply by the injection of a small amount of the killed organisms a certain degree of immunity against the natural mode of infection is acquired, Dr. Strong thinks it probable that by the use of his

prophylactic human beings may acquire a good active immunity against the disease.

The Centenary of the "Edinburgh Medical Journal."

The part played by Scotland in the development of medical knowledge is so important that a review of the achievements of her medical men during the last century forms most interesting and instructive reading. The names of the Munros, the Duncans, the Bells, Liston, Syme, and Simpson, are all so intimately connected with the history of medical progress that they are familiarly known the world over, yet they are but a few of those who have caused Scotland to shine with the reflected glory of their attainments. How much work was done by these men and their colleagues may be appreciated by inspecting the centenary number of the *Edinburgh Medical Journal*, issued to commemorate its one-hundredth anniversary. It was under the editorship of the younger Andrew Duncan that the *Edinburgh Medical and Surgical Journal* first saw light as a quarterly magazine in January, 1805. After various vicissitudes and changes of name, in 1855 the Journal was amalgamated with a younger monthly rival and called *The Monthly Journal of Medical Science*, and after July of that year the successor of the two periodicals received its present title, as the *Edinburgh Medical Journal*. The January number of this year contains a general historical survey of the growth of the journal, together with thirteen portraits of its various editors during the century; the remainder of the space being occupied by special articles devoted to each branch of medical work, and outlining the purport of the more important contributions on each subject that have appeared in the journal. These pages make fascinating reading as they record the many controversies waged on such hotly contested topics as the value of venesection, the methods of performing lithotomy, the interpretation of heart murmurs, the nature of nephritis, etc.; or recall Astley Cooper's celebrated case of ligation of the abdominal aorta, Colles' description of the fracture that bears his name, Liston's account of the famous case in which he amputated through the thigh, single-handed and without a tourniquet, Syme's many memorable essays, including his description of the first amputation at the hip-joint done in Scotland, which he performed at the age of twenty-four, Lister's studies on inflammation, Simpson's work on anesthetics, etc. To do justice to the list of famous contributors and epoch-making papers would require reproduction of the entire one hundred and thirty-six pages of the original, which forms a most scholarly contribution to the history of medicine. It is a pleasure to congratulate our venerable contemporary on a past so replete with greatness, and to express the conviction that its future will prove to be not less brilliant.

Evolution of Psychiatry.

In an interesting paper with this title, read by Dr. William Francis Drewry, of Petersburg, Va., at the fourth annual meeting of the Tri-State Medical Society of the Carolinas and Virginia, it is stated that the first movement on this continent toward establishing an asylum by public authority was made by the Colony of Virginia in 1769. By the end of the eighteenth century there had been built in this country four public asylums for the insane, one each in Pennsylvania, Virginia, New York, and Maryland. To-day there are about one hundred and sixty public and many private institutions for this class of unfortunates. About 1840 marked the beginning of a new epoch in the care of the insane. In 1844 the Association of Medical Superintendents of American Institutions for the Insane was organized, and since that time State hospitals have sprung up in all parts of the United States. The colony system, initiated in Gheel, Belgium, has also taken firm root here. Dr. J. W. Babcock of South Carolina was the first to advocate separate provision for the insane who were suffering from tuberculosis. Recently, this plan has been adopted in several State hospitals, notably at the Manhattan State Hospital, New York, and in Indiana. Many of the States have established separate institutions or made special provision for the criminal insane. Among such States are New York, Michigan, Massachusetts, Illinois, North Carolina, Iowa, Maine, and Ohio. Separate institutions have also been established in different parts of the country for sane or insane epileptics, or for both classes. Dr. Drewry calls attention to one conspicuous blot in the administration of State Hospitals, namely, that the practical politician has seized the opportunity to come in for the "loaves and fishes." On more than one occasion the Medical Record has referred to this matter editorially and deplored the fact that such should indeed be the case. One would think that the spirit of greed might at least be held in restraint in dealing with those unfortunate beings whose reason has been overthrown. If, however, selfish considerations continue to prove stronger than humanity, the only remedy would appear to be so to influence public opinion that the people at large would insist that all public charitable institutions, and especially State Hospitals, should be administered solely in the interests of their inmates, irrespective of political influence.

Peripheral Nerve Intoxication.

A few years ago an epidemic of this condition occurred in certain parts of Great Britain. To the satisfaction of most investigators the affection was traced to the consumption of beer which, when analyzed, was found to contain arsenic in toxic quantities. *The Lancet* of December 10 has an abstract of a chemical lecture delivered by Dr. Henry Waldo bearing upon the subject. The physician in question points out that on the occasion of the wholesale occurrence of peripheral neuritis in the vicinity of Manchester in 1901, when the concensus of opinion leaned to the view that arsenic and not beer was responsible in most of the cases, Sir William Gowers drew attention to the fact that the trouble does not often follow the prolonged use of Fowler's solution in combination with bromides in epilepsy.

Dr. Waldo cites a case under his care of a young man who was attacked by peripheral neuritis, one of the symptoms of which was paralysis of the extremities. The condition was caused by alcohol alone. The writer describes the symptoms which are those of severe nerve intoxication, and mentions that the legs are so extremely paralyzed that it is often feared the mischief may have ascended to the spinal cord and invaded the anterior cornual cells. Nevertheless, the prognosis is favorable, and Dr. Waldo is of the opinion that complete recovery is the rule. Referring to treatment, the statement is made that the one all important factor is rest in bed. Morphine may be given if the pains are acute, but before this, hot-water fomentations should be tried. A daily warm bath is recommended after the acute symptoms have passed, and if the tenderness is not extreme, gentle massage may be used. In the case cited slow interruptions of the constant current

battery were being used, in order to prevent the muscular substance from degenerating, but when reaction to an induced faradic current, which acts indirectly through the medium of a nerve twig, can be obtained, that form of electricity should be employed. Strychnine should not be used during the acute stage of the illness, and arsenic not at all.

Leprosy in the Sulu Archipelago.

Assistant Surgeon J. W. Amesse, of the Public Health and Marine Hospital Service, contributed to its last annual report a paper on this subject. It appears that leprosy has existed in the Sulu group since early in the eighteenth century, and before the arrival of the Chinese, although it is certain that they have been an important factor in the spread of the disease since the establishment of their trading centers in 1755. Dr. Amesse thinks that the first cases were conveyed by Moro pirates, and it is also probable that Javanese lepers, escaping from their own country, where lazarettos were in vogue as early as 1657, established themselves in neighboring islands and contributed to the infection of Sulu. "Later on," says the writer, "when the Spanish Government founded penal colonies in the island of Mindanao and garrisoned its outposts with Tagalog and Bisayan soldiers recruited from provinces where leprosy was common, numerous cases appeared among the Filipinos, but at no time was segregation of these unfortunates attempted." The Moros recognize both forms of the disease under the general name "epul." They believe that leprosy can originate *de novo* or through sorcery or the enchantment of some enemy; that it may follow continued and intimate association with one already stricken with the tuberculous form, or may be caused by a fish diet, especially when restricted to one species. Another reason assigned for the presence of sporadic cases is the visitation of divine wrath following certain personal pollutions forbidden by the Koran with even greater emphasis than are similar transgressions in the Bible of the Christians.

Loss of Life at Sea.—Apparently ocean travel is becoming less dangerous, though this can hardly be said of railroad travel, in this country at least. An official return shows that fewer lives were lost at sea in 1903 than in any other year during the last twenty-five. The number of lives lost was 624, of which 599 were sailors and 25 passengers. The annual average for the last twenty-five years is 1,613 lives. Other figures show that there were 5,765 accidents sufficiently serious to be recorded. Of the 350 vessels which were total losses, 70 foundered, 188 stranded, 56 were sunk in collision, and 18 disappeared. Of the lost, 2 had been sailing safely for sixty years, 5 for more than forty years, and 21 for over twenty years. There were 5,660 lives saved along the British coasts. Of this number the rocket apparatus saved 235, lifeboats rescued 489, the coast guards picked up 205, passing ships saved 578, and 1,100 reached safety in the boats of their own ships.—*The Sun.*

The Plaquemines Parish, La., Medical Association held its semi-annual meeting at Pointe-a-la-Hache, on January 20, and elected officers for the ensuing year as follows: *President,* Dr. J. K. Johnson of Buras; *Vice-president,* Dr. V. O. Schayot of Pointe-a-la-Hache; *Secretary-Treasurer,* Dr. H. L. Ballowe of Diamond.

News of the Week.

Sanitary Legislation in Pennsylvania.—A bill has been introduced into the Pennsylvania Legislature providing that in cities of the first class the Bureau of Health shall have supervision over the sanitary condition of all premises, wagons, carts, and receptacles used for the sale and distribution of milk or any of its fluid derivatives. Permits are to be granted by the Bureau of Health for such premises or vehicles after inspection. Violation of the act is punishable by a fine of from $5 to $25, or by imprisonment for five days for each offence. Another bill has been introduced providing that in cities of the first class the health authorities may from time to time, when they shall deem it necessary to prevent the spread of smallpox, issue an order requiring all citizens to be vaccinated within such time as they may prescribe, excepting such persons as can prove that they have been successfully vaccinated within five years. The penalty for refusal to obey such order shall be a fine of not less than $5 nor more than $25, and provision is made that any person unable to pay for such vaccination shall be vaccinated free.

National Red Cross Society Reorganized. — The first meeting of the American National Red Cross under its new charter was held in Washington, February 8. Extensive plans for reorganization were discussed and the following officers elected: *President,* Secretary of War W. H. Taft; *Treasurer,* Assistant Secretary of the Treasury C. H. Keep; *Counsellor,* Assistant Attorney-General Louis Pratt; *Secretary,* Charles L. McGee; *Executive Committee,* Assistant Secretary of State Francis B. Loomis, Brig.-Gen. George W. Davis, U. S. A., Medical Director John C. Boyd, U. S. N., Chief of the Bureau of Corporations James R. Garfield, Hilary A. Herbert, former Secretary of the Navy, Miss Mabel Boardman of Washington ,and Surgeon-General Wyman of the Public Health Society. One of the suggestions made was that central storehouses for Red Cross supplies be established in various parts of the country for use in emergencies. By-laws to govern the society were adopted. It is the plan of the organization to begin an active campaign in every State and Territory for the upbuilding of the Red Cross Committees of twelve in each State are planned.

The Moscow Physicians on the Side of Liberty.—At a meeting of medical men residing in Moscow and its neighborhood, held on February 10, a series of resolutions was passed for presentation to the Moscow Zemstvo, indorsing the demands made by the workingmen of St. Petersburg on January 22. The resolutions express indignation at the methods of the bureaucracy, "whose aim is the suppression by violence of all attempts of the nation to secure political liberty," and announce the determination of the physicians to aid the liberal movement, although they cannot strike because they cannot leave the Muscovites without medical aid. The resolutions also express the opinion that the war should be stopped as quickly as possible, and say that to this end the Zemstvo ought to refuse to contribute further money to the medical service in the Far East, "thus actively opposing a continuance of the war, which is both foreign and perilous to the interests of the Russian nation."

Disinfection of Confessionals.—A telegram to the *New York Times* from the City of Mexico announces that the Government authorities, acting upon the recommendation of the Board of Health, have issued an order for the disinfection of confessionals in all churches of that capital daily.

Priests in charge of churches who neglect the order will be fined and imprisoned. The health authorities say that the confessionals help the spread of contagious diseases. A similar order has been issued in the City of Guadalajara, and it is the intention to put it into effect throughout the republic. This is an example of progressive hygiene which may well be followed by sanitarians generally.

Vital Statistics of Philadelphia.—Diseases of the respiratory tract are still responsible for a large share of the mortality. Thus, among 612 cases deaths reported to the Philadelphia Bureau of Health for the week ended February 11, 95 are attributed to pneumonia, 67 to pulmonary tuberculosis, 22 to broncho-pneumonia, 15 to congestion of the lungs, 13 to influenza, 13 to acute bronchitis, 6 to chronic bronchitis. Diseases of the heart and arteries constitute the group contributing the next largest number of deaths. Heart-disease is made responsible for 68, apoplexy for 26, diseases of the arteries 13, endocarditis for 5, angina pectoris for 3. Fifty deaths are charged to Bright's disease, 3 to acute nephritis, 2 to other diseases of the kidneys. Carcinoma in various situations caused 12 deaths, old age and congenital debility each 12, gastro-enteritis in children 11, diphtheria 11, typhoid fever 8, appendicitis 8, diabetes 7, convulsions in childhood 7, meningitis 7.

The American Antituberculosis League.—The next meeting of the American Antituberculosis League will be held in Atlanta, Ga., April 17 to 19, 1905. Governor J. M. Terrell has tendered the Hall of the House of Representatives to the Georgia State Capitol for the use of the League during the meeting, and he will deliver an address to the League at the opening session. Papers have been promised by a number of physiologists of this country and Europe, among the latter Dr. Linet of Paris, who will describe a new method of treatment of tuberculosis which, he claims, to be very successful. The president of the League is Dr. George Brown of Atlanta, and the chairman of the executive committee, Dr. J. H. Hallock of Saranac Lake, N. Y. The Georgia State Commission on Tuberculosis and the Georgia Antituberculosis League will meet at the same time and place.

An Object Lesson in Rabies.—The medical class of Bowdoin, numbering about one hundred students, was imprisoned in the lecture-room the other day by a bulldog which was thought to be mad and which was running through the corridors of the building. The dog was finally killed by the janitor and the students were released.

Tuberculosis in Boston.—At a meeting of the Brookline, Mass., Medical Society, on February 8, Dr. Edward O. Otis presented a communication on tuberculosis. He said there were more than three thousand persons in Boston suffering from pronounced tuberculosis in its various stages. The deaths from the disease in 1903 numbered 1,227, and in 1904 11½ per cent. of all the deaths in Boston were caused by tuberculosis. Most of the hospitals closed their doors to sufferers from this disease, and consequently provision for the care and treatment of consumptives was totally inadequate, notwithstanding that special provision was made for them by the pauper and penal institutions of the city and that a few patients were received in the private hospitals.

Officers of the Chicago Laryngological and Otological Society.—At the annual meeting of this Society, recently held, Dr. Wm. L. Ballenger was elected President and Dr. Geo. E. Shambaugh, Secretary.

Phipps Institute for the Study, Prevention, and Treatment of Tuberculosis.—According to the report for the year 1904, 2,039 patients were under observation, of whom 1,130 were native-born and 769 were foreign, while of 140 the nativity was not recorded. Many of the foreign-born had been in this country for so short a time that it is assumed they were infected before landing. Of the entire number 6½% were negroes—a larger proportion than that of the negro to the white population of the city. Improvement took place in 537 patients, no improvement in 583, the result was not recorded in 884, and death resulted in 153.

Award of the Samuel D. Gross Prize.—Announcement is made that the Samuel D. Gross Prize of the Philadelphia Academy of Surgery for the year 1905, amounting to $1,200, has been awarded to Dr. James Homer Wright of Boston, Mass., for his essay, "The Biology of the Microorganism of Actinomycosis."

Legislation to Restrict the Sale of Cocaine.—Alderman Ryan, of Chicago, recently proposed legislation to prohibit the sale of medicines which contain too great a percentage of cocaine. His proposition was submitted to a meeting of a sub-committee of the License Committee of the City Council. It was asserted that many medicines are bought merely for the sake of the cocaine they contain, and information was obtained especially regarding one article sold as a remedy for catarrh which is used almost exclusively by those addicted to the cocaine habit.

An Epileptic Colony in Indiana.—The Legislature of Indiana has made an appropriation of $150,000 for the establishment of a State colony for epileptics. Senator Purviance was the introducer of the bill.

The Sixth District Medical Association of South Carolina.—This association, embracing the counties of Chesterfiely, Marion, Marlboro, Horry, Darlington, and Florence, was organized at a representative meeting of physicians of the district at Florence, S. C., on February 7. At the morning session Dr. J. F. McCormack of Bowling Green, Ky., delivered an address on "The Necessity of Organization Among the Medical Profession." The following officers were elected: *President,* Dr. Frank H. McLeod of Florence; *Vice-president,* Dr. A. T. Baird of Darlington; *Secretary,* Dr. J. M. Earle of Darlington. The next meeting will be held October 2, at Florence.

The Cincinnati Academy of Medicine.—At the regular meeting, on February 6, Dr. H. J. Whitacre reported a case of strangulated femoral hernia associated with a littre hernia which was gangrenous just above it, and above that a stricture of the bowel only admitting a small lead pencil. The patient recovered. Dr. Rufus B. Hall reported a case of soft myoma uteri and one of multiple myoma uteri with the ureter stretched over one of the nodules. Dr. C. L. Bonifield reported a case of very large submucous fibroid protruding through the cervix with pyosalpinx due to infection from the protuding mass. Dr. Tate read a paper on puerperal eclampsia and reported a number of cases.

Prophylaxis of Venereal Diseases.—The Ohio State Board of Health has issued leaflets to physicians, requesting that they be given to all patients suffering from venereal diseases. These leaflets contain information about the general hygienic measures that should be observed to prevent harm to the patient and his surroundings.

Indian Girls for Nurses. — Indian Commissioner Leupp has asked Congress for an appropriation of $20,000 for a new hospital at Carlisle, Pa., where the sick among the Indian students may receive

treatment, and where Indian girls may be trained as nurses. There is excellent material in them for work of this kind, the Commissioner says, for they are not sentimentally sympathetic, though kind, and will obey implicitly the orders given by the physicians under whom they serve.

Spotted Fever in Maine Lumber Camps.—It is reported that cerebrospinal meningitis has assumed an almost epidemic prevalence among the lumbermen in the Maine woods. A number of deaths have occurred and many of the camps have been nearly deserted by the men who have returned to their homes to escape infection.

Calorimetric Observation on Brain Work.—One of the students at Wesleyan College in Middletown, Conn., was recently examined in one of the branches while seated in a calorimeter. The purpose of the experiment was to determine the amount of mental energy expended while working out the answers to the examination questions.

Yellow Fever in the Harbor.—A sailor on the *Orizaba* from Colon was found to be suffering from yellow fever when the vessel arrived here last week. He was removed to the quarantine hospital, and the steamship was allowed to land her passengers and cargo.

A Tax on Cigarettes.—The newspapers announce that it is the intention of State Excise Commissioner Cullinan to ask the New York Legislature to impose a special tax on the sellers of cigarettes. His alleged reason is that such a tax will add largely to the revenues of the State. But it would be interesting to know why dealers in cigars, smoking tobacco, chewing tobacco, and snuff are not also to be taxed, and whether the commissioner does not hope deep down in his boots to put a stop to cigarette smoking which he possibly thinks is more injurious than any other way of using tobacco.

Obituary Notes.—Dr. Frank Cowan of Greensburg, Pa., died at his home in that place on February 12 after an illness of several months. He was born in Greensburg in 1844 and was graduated in medicine from the University of Georgetown, D. C., in 1869. He was also graduated in law, edited a newspaper, traveled extensively, wrote verses, romances, a book on insects, compiled a dictionary of sea proverbs, and was an enthusiastic fruit cultivator.

Dr. Hollis S. Kezar of Elko, Ga., died on February 1, at the age of eighty-two years. He had practised medicine for over fifty years, and was also a large landowner and planter.

Dr. J. B. Howard Gittings died at Philadelphia on February 9 at the age of sixty-three years. He was graduated from the medical department of the University of Pennsylvania in the class of 1863.

Dr. Frederick Tuxbury died at Denver on February 5, at the age of thirty-seven years. He was born at Allen's Corners, Mass., and was graduated from the Dartmouth Medical School in 1898.

Dr. Frank H. Sims of Atlanta, Ga., died on January 29 of pneumonia, at the age of forty-two years. He was born in Mobile, Ala., and was graduated from the Southern Medical College, Atlanta, in the class of 1883.

Dr. Peter Roosevelt Johnson died at his home at Sag Harbor, L. I., on February 13, at the age of seventy-seven years. He was a graduate of the College of Physicians and Surgeons in New York, but had not practised medicine for several years.

Dr. Abner R. Wellborn died at Columbus, Ga., on January 31, at the age of eighty-three years. He was a graduate of the New York University Medical School in the class of 1841, and practised in Atlanta until his retirement from active work five years ago.

Dr. Alexander Ramsay died at Philadelphia on February 12 at the age of fifty-four years. He was for ten years superintendent of the Insane Department of the Philadelphia Hospital and he was graduated from the Medico-Chirurgical College in 1892.

Dr. Edward Dudley Arnold of Omaha died of pneumonia on February 3. He was born at Keokuk, Ia., in 1858, and removed to Brownville, Neb., in 1868. He graduated from Ann Arbor College in 1877, and from Rush Medical College in 1878, removed to Omaha in 1883, where he had since resided.

Dr. Thomas F. Padula of Quincy, Mass., died suddenly on February 9, of disease of the heart. He was born in Naples, Italy, December 9, 1859, and came to this country when a lad of ten years. He was a graduate of the Harvard Medical School in the class of 1887. He began practise in Neponset, but removed to Quincy in 1893.

Dr. James A. Freer, a well-known homeopathic physician of Washington, was found dead at a country inn on the Tennallytown road where he had passed the night. He was born in Gilbertsville, N. Y., forty-six years ago, and was graduated from the New York Homeopathic Medical School and Hospital in the class of 1881.

Dr. J. Leslie, a well-known dentist of Cincinnati, died at the age of eighty-six years on February 8. In 1877 he was awarded a diploma by the Vienna Exposition for the discovery of a crystalline form of gold for filling teeth. He was one of the professors at the Ohio College of Dental Surgery and president of the Ohio Mechanics' Institute.

Dr. Thomas H. Sherwood, for many years a medical examiner in the Pension Bureau at Washington, died at his home in that city on February 10. He was a native of Delaware, was graduated in medicine at Philadelphia, and in 1861 was assistant surgeon of the Third Pennsylvania Cavalry. He also served as surgeon of the Twenty-seventh Pennsylvania Infantry and was mustered out in 1865 with the brevet rank of Captain for faithful and meritorious service during the war.

Dr. William H. Risk died at his home in Summit, N. J., on February 7, after a long illness. He had been president of the Board of Health of Summit for two years. He was born in 1842 and was educated in Lafayette College and graduated in medicine from the University of Pennsylvania in 1866. He lived in Philadelphia many years and went to Summit in 1873. He was consulting physician to the Fresh Air and Convalescents' Home at Summit, director of the Summit National Bank and a member of the school board. He was also a member of the Morris County Medical Association and the New Jersey State Medical Society.

Dr. William Johnston died in St. Louis on January 31 at the age of ninety-one years. He was born in Oldham County, Ky., and was graduated from the Medical Department of the University of Louisville in the class of 1838. He began practice in St. Louis in 1851. About two years ago the St. Louis Medical Society, of which Dr. Johnston was formerly president, and an active member up to his last illness, tendered a banquet to the four octogenarian physicians of St. Louis then living. They were Doctors J. B. Johnson, Samuel Pollak, W. M. McPheeters, and William Johnston. Since then all have died save Dr. McPheeters.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

FEEDING SCHOOL CHILDREN—INJURIES FROM ELECTRICAL CURRENT—GAERTNER'S BACILLUS IN MILK—ASCENDING PARALYSIS IN CYSTITIS—SIR W. PREECE AND ELECTROTHERAPEUTICS—BURIAL ALIVE.

LONDON, January 27, 1905.

SIR JOHN GORST is carrying on his campaign for feeding the school children, undeterred by the prospect of losing his seat in the House of Commons. One can hardly wonder that his constituents are somewhat shocked, especially at his presiding over a meeting of a socialistic association for the sake of advocating his views. Voters are asking if they are to pay for food will not the next demand be for clothing.

It is less surprising to find Mr. Jonathan Hutchinson among the socialists. On Monday he addressed the Independent Labor party, and said it was useless as well as cruel to ask attention to lessons from a hungry child. He would not stop at seeing that the scholars were none of them breakfastless, but would provide them with dinners in school at the public expense. He said it would be an excellent investment to equip the next generation so much better for the battle of life. Ratepayers are shaking their heads, and when Sir J. Gorst and others estimate the cost at a halfpenny rate, say they remember that in parliament when the great education scheme of 1870 was carried, they were told the cost would never exceed a threepenny rate, but now it is more than five times as much, and ever rising. Mr. Hutchinson says feeding the children will no more pauperize the parents than providing museums and picture galleries. He wants every school to have a museum. The more expensive objects he would let circulate from one school to another. Nor were these the only changes he advocated. He is for a sweeping reform in our examination system. He seems to have no confidence in examiners—and he certainly should know something of them. He says the candidates' chances depend too much on the individuality, not to say the caprices and prejudices of the examiner. So he would not permit any extemporary questions to be asked. Lists of carefully considered questions should be prepared and no others allowed to be put. Mr. Hutchinson has never hesitated to express views which were not likely to be generally accepted, so it is scarcely worth while to discuss whether his latest proposals will meet with approval.

With the rapid extension of great electrical works come reminders of the dangers attendant. Some accidents give rise to unexpected injuries, and others destroy life at once. An instance of the former which caused considerable comment in the papers, has now been related at the Clinical Society by Mr. Lucas, under whom the patient was received at Guy's Hospital immediately after the accident. He was a strong young fellow of 15½ years, who slipped while at work, and his right hand came in contact with the main cable carrying the current of 10,000 volts for a period estimated as thirty seconds. He was laid down, rigid and apparently lifeless, and the limbs were burnt, swollen, and stiff; artificial respiration was immediately begun, and consciousness returned. He was taken to the hospital, and soon showed signs of shock, and all his limbs were gangrenous. On the third day the right arm was amputated, and arterial thrombosis was seen up to the origin of the superior profunda. He bore the operation well, and the next day sat up in bed. Three days after the amputation, six after the accident, the gangrene of the feet and legs was spreading, and the temperature had risen to 101.4° F. Both legs were amputated simultaneously, and this operation was well borne and the shoulder wound progressed favorably. Two days later signs of toxic infection appeared and the temperature rose to 104.2°. Death took place on the ninth day after the accident. Mr. Lucas mentioned some other cases lately reported, mostly from "live rails."

Mr. F. Aspinal spoke as an engineer, and divided accidents into groups according to whether the current passed through the body or not. When a high-tension current passes, the victim may make either good or bad conduct. So, too, with low tension. He classed all currents above 750 volts as high, but voltage was not the chief factor. The contact was the point. He said patients severely burnt showed less shock than when there was little external injury. He described the "cry" in these accidents as peculiar—a sort of inspiratory shriek. He said when an arc was formed metals were volatilized, and suggested that their vapors might cause death.

Dr. W. J. Harris thought the chief factor was the amount of current which passed through the body. A low-voltage current might produce fatal shock, while recovery sometimes followed when a current of [illegible] passed through the body.

Dr. Jellinck of Vienna communicated through Mr. Spencer some observations to the effect that much depends on the resistance. The resistance was that of entry and that of exit. The former, referring to clothes and skin, whether wet or dry; the latter varied with the ground, and often the foot-covering. He mentioned a case of a man killed by 95 volts when standing barefoot on a mixture of [illegible] and sugar. In contrast, another man was much injured, but not killed, by 5,500 volts. The dry, horny palm of a workman might offer a resistance of entry of 100,000 ohms; the mucous membrane of the mouth not more than 1,000. Rooms and shops containing electrical installations should be distinguished as safe or dangerous, according to the tension of the current and the nature of the ground.

Dr. E. Klein recounted at the last meeting of the Pathological Society a series of observations showing that Gaertner's bacillus is often present in cow's milk. Out of thirty-nine samples from farms in different counties, no less than ten contained the bacillus. Guinea pigs injected with the sediment developed a chronic disease—enlarged spleen with miliary purulent nodules. These contained numerous bacilli enteritidis Gaertner, as proved by cultures in all media, by standing, by agglutination, as well as by injection and feeding of mice and guinea pigs with cultures.

It was further shown that the chronic disease was produced by relatively small numbers of the bacilli in the milk. When given minute doses of cultures the animals survived and after eight days began to develop miliary nodules of the spleen; but large doses caused acute septicemic infection and death. It is not a pleasant reflection that such milk kept in a warm place or in the warm time of the year would be an excellent medium for the multiplication of the bacilli, during which process the appearance of the milk might remain unchanged.

At the Clinical Society Dr. T. J. Walker described three cases of acute ascending paralysis which terminated long-standing chronic cystitis. One was in a man who at the age of fifteen had injured his urethra by falling upon a rail and was treated for recurrent stricture and cystitis from his twenty-fifth to fortieth year. He was under treatment for such an attack when in the night he felt a numbness and loss of power in the legs. In the morning there was paresis up to the thighs and by evening up to the arms and thorax, the breathing became embarrassed and he died eighteen hours after the onset of paralysis. The other two cases resembled this—paralysis coming on in the course of cystitis of long standing, rapidly spreading upwards and proving fatal in a few hours. Dr. Walker referred to two cases he had found in the records and suggested that the cause was the extension of microbes from the bladder to the spinal cord.

Mr. C. Lucas suggested that the paralysis might not be due to the cystitis, but perhaps to exhaustion from long illness.

Dr. E. F. Buzzard said there were three different forms of ascending paralysis, one of which was a meningomyelitis. It occurred as a result of infection by various organisms and he thought Dr. Walker's cases were such.

Mr. Spencer said experimental rabies terminated in ascending paralysis. Many toxins might probably produce it.

Yesterday Sir William Preece opened a new pavilion for electrical treatment at Cardiff Infirmary. He said nothing was more wonderful than the rate at which therapeutical progress had gone on of late years. The more he used electricity the more he was astounded. The wonders of telegraphy and telephony were overshadowed by the Roentgen rays, which enabled one to see the invisible mechanism of the living body. How foolish were those who would prevent experiments on animals, sacrificing the lives of men to save a dog. Radium had not proved the good friend it was expected to be. It was now regarded rather as an enemy, because it had brought out certain dangers which were never anticipated.

There is a small society here which has for its object the prevention of live burial. It held its annual meeting yesterday and, as the papers this week had reported the case of a patient whose funeral had been arranged, but who was not dead, the speakers would indulge in unpleasant suggestions which seemed opportune. The society has now adopted a more reasonable attitude and will direct its attention to an effort to reform our registration laws, which are very lax.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

COPPER TREATMENT OF MANILA WATER—LEPROSY—CULTIVATION OF THE BACILLUS LEPRA—LEPROLIN—BOARD OF HEALTH CHANGES.

MANILA, P. I., December 28, 1904.

THE experiment of mixing sufficient copper sulphate with the water supply of the city of Manila, to make a solution

of 1 to 4,000,000, has now been carried on for a period of eight weeks. Samples of water were taken once a week at three different sections of the city and were regularly examined. The results so far as amœbæ are concerned were not at all encouraging. Amœbæ were found in the water before copper sulphate was introduced and in the twenty-four examinations which were made subsequently they were found present each time with one exception, and in that instance the amœbæ were present in two out of three samples that were taken the same day. Furthermore, in samples of water treated with copper sulphate in solution of 1 to 100,000, over a period of three days, the amœbæ were found apparently just as numerous as in the control. Thus it will be seen that whatever other virtues copper sulphate may possess, it is practically of no service in the destruction of amœbæ. There seems, however, to have been a reduction in the number of bacteria. At the beginning of the experiment, samples of water taken at three different sections of the city showed 340, 150, and 184 bacteria per c.c. respectively; while toward the close of the experiment the figures were 120, 60, and 65 respectively. In other words, out of twenty-one bacteriological examinations made subsequent to the first one, the bacteria were found to number less than 100 per c.c., on fifteen occasions, and of the remaining six they never reached above 140. Thus it will be seen that by contrasting this latter number with the 340 originally found, a marked reduction has taken place. It is understood that before the copper sulphate was used, the bacteria were almost invariably above 100 per c.c. It has also been reported that the copper sulphate in these high dilutions caused a marked decrease in the number of infusoria.

Considerable attention has been given here to the two publications on leprosy by E. R. Rost, Capt. I.M.S., Resident Medical Officer, General Hospital, Rangoon, which appeared in the *Indian Medical Gazette,* No. 5, of May, 1904, entitled "The Cultivation of the Leprosy Bacillus;" and in No. 6, of June, 1904, "Further Notes on the Cultivation of the Bacillus Lepra and the Treatment of Leprosy by the Injections of Leprolin, Manufactured from Cultures." The author states that just as there is a class of bacteria which may be classified as anaërobic, so there is a class of bacteria which may be classified as achloretic. Of these the bacillus of tuberculosis, leprosy, and syphilis are pathogenic. He claims to have successfully cultivated lepra bacilli by growing them in media made with the ordinary beef extract, from which the salt has been extracted by distillation. For this purpose of cultivating them the lepra bacilli were obtained from fresh granulating sores of leprous subjects. After being implanted on the foregoing media the growth appeared as a white, stringy, streaky, heavy deposit at the bottom of the tube at the end of two days and was difficult to shake up. On microscopical examination the bacilli were characteristic, being very resistant to acid. He also grew them on agar, from which the salt had been extracted by dialysis. The growth appeared on the surface after two days' incubation at 37° C., as very slightly yellowish and beady. He then proceeded to make leprolin on the same general principles as the tuberculin made by Koch. The lepra bacilli were permitted to grow in the distilled beef extract at 37° C. for six weeks, then sterilized and passed through a Pasteur filter, after which glycerin was added to clear the fluid. In his second paper he claims to have improved the foregoing method by dispensing with the sterilizing, and instead refiltering the leprolin through fresh sterilized filters, then the bulk is reduced to one-tenth of the original amount by exhaustion over sulphuric acid in vacuum. The fluid is then mixed with an equal quantity of glycerin and kept on ice until used. The injection of 10 c.c. of this solution is said to cause violent reactions in cases of leprosy, the temperature rising to 104° Fahr. and the leprous patches becoming red, hot, and swollen. He states further that thirty-five lepers have been injected with leprolin. He gives notes from twenty-four of those cases and notes that in most of them the injections have been followed by marked improvement and that a few of the cases have been almost completely cured. An analysis of the notes, however, shows that the diagnosis is not well established. A careful perusal of his papers shows them to be extremely crude and the scientific data not well supported. It is, however, possible that the author has made an important discovery and has been unfortunate in his presentation of the matter. Judging by some preliminary work done here, in accordance with his published directions, it would seem that there has been an error in his technique, which has caused certain forms of streptococci to be mistaken for leprosy bacilli. It is only fair to state, however, that as yet this has not been confirmed. The local health authorities are considering the advisability of trying some of the leprolin on a few cases of leprosy and if this is done the matter will be reported upon later.

Mr. Henry D. Osgood has resigned his position as sanitary engineer of the Board of Health of the Philippine Islands, and will return to the United States in January. Mr. James D. Fauntleroy, formerly of the Bureau of Engineering, has been appointed to succeed him.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

UNFAVORABLE OUTLOOK FOR BERLIN PHYSICIANS—DER BUND FUR MUTTERSCHUTZ—TRANSPORTATION OF THE SICK—WINTERERHOLUNGSSTATTE—SYPHILIS AS AN OCCUPATION DISEASE—WHEN SHALL WE OPERATE IN APPENDICITIS—THE RÖNTGEN CONGRESS.

BERLIN, January 23, 1905.

THE new year does not seem to be opening propitiously for Berlin physicians. As I have stated before, many of us are deprived of a large part of our legitimate income. Although the physicians in the more exclusive parts of the city are not affected, still, the unfavorable condition is widely recognized, as can be seen by the last state publication, which was issued in April, 1903. Up to this time, 545,347 men have become members of lodges, forty per cent. of whom have been ill. Notwithstanding their difficulties, physicians have been loyal to and have worked for the state's best interests.

The latest Berlin charity among the more prominent physicians is "Der Bund für Mutterschutz." The outlook is encouraging, and the success bids fair to continue. The pamphlet, signed by our most respected physicians, professors, and authors, explains the object of the charity. About 180,000 illegitimate children are born every year in Germany. About 28.5 per cent. of these illegitimate children die in the first year, while only 16.7 per cent. of legitimate children die. A small part of the illegitimate children become soldiers, but by far the greater number form our criminal and tramp population. On account of the decrease in birth rate, it behooves us to foster every healthy child for the sake of the state. For this purpose "Der Bund für Mutterschutz" encourages the erection of homes for unmarried mothers, where they can support themselves and their children by farming or factory work. The professional advice of doctors and lawyers is provided.

The science of hygiene is advancing in Berlin. The subject of the transportation of the sick has been undertaken by the "Verband für erste Hülfe." At present there are three places in town where ambulances can be procured. After each trip the ambulance can be disinfected. These vehicles will be used in preference to public cabs, and thus the liability of disseminating infection will be lessened.

The Red Cross has also founded a new institution. The first building has been erected in the Grunewald. It is a substantial building, with dining room and lounging rooms; in fact, a little hospital where patients come for the day, returning to town in the evening.

Of the papers read during the last year, Blaschke's is one of the most valuable. He presented it at the "Medizinische Gesellschaft." The topic was "Syphilis als Berufskrankheit der Aerzte." It deals with the origin, diagnosis, and prophylaxis of professional syphilis. The author cites twelve cases, ten of whom were in Berlin physicians. The first evidence of the disease is nearly always noted in the fingers, and is often mistaken for herpes, anatomical tubercle, and soft chancre. Herpes is preceded by neuralgia and is cured in from eight to ten days, and is followed by no sequelæ. The lack of adenitis is characteristic of anatomical tubercle. Soft chancre can be recognized by deep ulceration. In one of the cases he could find no portal of entry for the infection. But this might have been an insect bite. Blaschke has never seen or heard of infection from the puncture of a hypodermic needle. But he has seen a pathologist infected by a cadaver which he had dissected in the first twenty-four hours after death. He calls attention to the many little wounds so common on the fingers of physicians. After infection has occurred, he puts iodine into the wound or cauterizes the adjacent tissue. When physicians have syphilitic infection of the hands, they should not be allowed to do any work.

Rotter has recently read a paper before the "Freie Vereinigung der Chirurgen Berlins," entitled "Ueber die Frühoperation bei acuter Appendicitis in den ersten 24 Stunden." The opinions of the greatest Berlin surgeons were expressed on this occasion. A small number of excised appendices showed no microscopical changes, but the majority showed effects of pathological disturbance. In twenty-three cases there was no exudation in the peritoneum. Twenty-two cases were purulent. In most of the latter the appendix was perforated, six of these patients dying. On account of the difficulty of making a prognosis, immediate operation is the best therapeutic measure. In purulent exudation drainage is recommended. In the discussion, Sonnenberg advocated immediate operation only

in diffuse purulent peritonitis. In the other cases he saw no better results from operation than from expectant treatment. He declared that it was impossible to operate upon every paient suffering with pains in the abdomen. The prevailing opinion was in favor of immediate operation when the cases present themselves early for treatment, but later, operation should be delayed until a period free from fever.

The same evening Dirk read a paper on "Scopolamin-Morphine Narcosis." Two hours before operation he gives 0.0005 scopolamin, and 0.01 morphine, repeating this dose in an hour. This treatment diminishes the amount of ether necessary. The narcosis is profound and there is no vomiting. The later condition is very satisfactory. Slight cyanosis is common in this treatment.

A congress and exposition will be held on the tenth anniversary of Röntgen's discovery, which will be next April. Many brilliant workers will be there. Röntgen himself will be the honorary president. This congress will [illegible] with [illegible] surgeons.

Progress of Medical Science.

The Boston Medical and Surgical Journal, February 9, 1905.

A Case of Chylous Cyst of the Abdomen.—[illegible] Richardson describes this case. The patient was a boy of eleven years. He was rather thin and cachectic, with a very prominent abdomen. He was extremely emaciated. The thorax was much dilated over the epigastrium on both sides. The ribs were prominent. The abdomen contained fluid, and was much distended. The temperature was [illegible]. A diagnosis of tuberculous peritonitis was made. At operation, the writer went into the peritoneal cavity, finding none of the features which were so confidently expected to appear. Instead, there was noted a white, fragile-walled cyst covered with small blood vessels, most of them running transversely. The tumor filled the peritoneal cavity, and was seen to be retroperitoneal; it extended up under the liver, and to the right. The cyst was emptied through an incision in its wall, and the fluid from it measured eight pints. The fluid was milky. The sac was then dissected out. It did not in any way involve the mesentery. The boy made a rapid and satisfactory recovery. The writer emphasizes the possibility of mistaken diagnoses, and urges that there may be a glimpse of encouragement in apparently hopeless cases.

I. K. I. Method of Sterilizing Catgut.—F. W. Johns advocates this method of sterilizing catgut. He declares that in every case in which the method has been criticised, it has been the fault of the user, and not that of the method. In the first place, clean, strong gut should be used. He uses gut that is almost white; it has no odor and is free from fat. Before sterilization, each strand should be thoroughly stretched. In the method he describes, the gut should be wound on wide reels if possible, and too much gut must not be put on one reel, for the solution must find easy access to the deeper layers of gut. Before using, the gut should be swashed through sterile water, but not allowed to soak in it. The reel can then be placed on a sterile gauze pad, and after the operation dropped back into the common jar. The solution is: Iodine, one part; iodide of potassium, sufficient to saturate, and distilled water sufficient to make one hundred parts. Reels made of papier maché are found to give excellent results. The writer gives the advantages of this method as being the absolute certainty of a sterile gut, ease of preparation, healing by first intention, and an animal suture material that will not slip, and that will tie like silk. Large sized gut is sterilized to its very center. Gut sealed in tubes in the I. K. I. solution and kept out of the light, will become friable in about three months. This gut should not be used in plastic work in the vagina, as to those tissues the iodine is irritating, and thus an excellent culture medium is made for microorgani[illegible] The writer appends the favorable reports of Martina [illegible] Page on this method.

New York Medical Journal, February 11, 1904.

The Cerebellar Seizure (Cerebellar Fits), a Syndrome Characteristic of Cerebellar Tumors.—C. L. Dana refers to recent literature on the subject of fibromata of the cerebellopontine angle, and gives a report of one personal case, presenting the peculiar syndrome named in the title of his paper. He believes that vertigoes and seizures of this kind are not unfrequent. The special feature in the tumors of the posterior cerebral fossa and of the cerebellum which cause irritation and pressure, is a seizure characterized by (1) Loud, high pitched tinnitus or roaring and crackling noises, suddenly increased in intensity. (2) Vertigo, usually objective, and with or without forced movements. (3) A tendency to drop or fall in one direction or another instantly to the ground. (4) Sometimes sudden blindness and loss of consciousness. (5) In severe attacks, tonic spasms g[illegible]erally of an extensor type. This lasts from one or two to five or ten minutes.

The Diagnosis of Cerebellar Tumors.—[illegible] Fraenkel notes that while headache, vomiting and optic neuritis are early and obstinate symptoms in cases of cerebral lesions, the opposite is true in positive and medullary lesions. Headache, if present, is generally occipital, and it together with vomiting in lesions of the posterior cerebral fossa, is most distressing in the morning after rising or a change of position. Attacks of amyasthenia and general vertigo are frequent expressions of cerebellar disturbance. Attacks of respiratory and circulatory disturbance with or without loss of consciousness, are not common. Trophic and visceral symptoms mostly accompany pontine lesions, very rarely cerebellar. Early evidences of irritation of cranial nerves, particularly the fifth and eighth pairs, are of great diagnostic importance as suggesting extracerebral disease while deafness, general locomotor incoordination disturbances of circulation and respiration, hemiparesthesias, or paralysis of conjugated ocular movements, introducing the disease, favor a diagnosis of the intracerebral origin. Of the extracerebral lesions of the posterior fossa, those originating in the basal nerves deserve distinction for various reasons. Excepting rare metastatic or primary lesions of the bone, and the less rare localized meningitis, the solid lesions of the pontomedullocerebellar angle are due to primary tumors of the fifth or eighth nerve. In many instances an exact diagnosis of an actual tumor is impossible, and the most we can say is that some lesion exists in the posterior cerebral fossa. Theoretically, it would appear that this fossa could be reached by the surgeon, but up to the present time there are on record but few instances of successful removal of growths from this locality.

The Functions of the Cerebellum.—E. Lodholz calls attention to the fact that the size of the cerebellum is not always proportionate to the variety of movements of its possessor. In frogs it is relatively small. In birds its lateral lobes are absent, while in the apes and man they are quite large. Lodholz describes the sequence of changes which follow the removal from animals of this portion of the brain, restlessness, irritability, moving or falling backwards, convergence of the eyeballs, etc. If the wound remains aseptic the tonic spasms become clonic or oscillatory, and the animal recovers locomotion and attitude to some extent. The cerebellum has no functions independent of its connection with the rest of the cerebrospinal axis. It contains the coordinating center, but if it is inactive, cells in other parts of the nervous system are capable of performing the functions assigned to it. A close functional relation exists between it and the semicircular canals. It has nothing to do with the sexual function. Motor impulses are undoubtedly strengthened in it, for its removal causes muscular weakness, described as due to three factors: Asthenia (weakening of muscular energy), atonia (lessening of muscular tone), and astasia (uncertain and unsteady movements). The organ does not, in all probability, contain any distinct center for the muscular sense.

Medical News, February 11, 1905.

Hematuria as a Symptom of Hydronephrosis; Nephrectomy; Cure.—L. Bolton Bangs calls attention to the fact that in the literature there is scarcely any mention of hematuria as a symptom of hydronephrosis. In the past few years he has found 13 cases reported, nine of which are by Israel. It would appear that hydronephrosis per se is a comparatively infrequent disease in this country. The patient whose history is here reported was a boy of nineteen years. He never had any sickness until the present one, which began about a year ago. He then complained of nausea and general malaise, and a sediment was noticed in his urine. A surgeon who was consulted said that there was blood in the urine. There was no history of traumatism, nor any history of renal colic or of pain in the left side, for by separating the urine of the two kidneys it w[illegible] discovered that the left kidney was the seat of the disease. Prior to the onset of the nausea and general malaise there was no symptom indicating the beginning of the malady. The time of the first appearance of blood in the urine is vague and indefinite. The patient suffered greatly with constipation, doubtless due to pressure of the renal tumor upon the descending colon. An exploratory incision w[illegible] made, and a bilobed, rounded tumor, with thin walls, was found. The walls were incised and about a quart of fluid escaped. The kidney was the seat of hydronephrosis, with comparatively little renal tissue left. Later the kidney was removed. A subacute pyelitis was present. No bacteria appeared to be associated with the kidney tissues. There was no neoplasm. At the operation there was an extreme amount of hemorrhage from the thin and expanded kidney tissue, the blood appearing to come from the interior of the sac, and not from its cut edges. The patient made a good recovery.

Two Cases of Tracheal Stenosis from New Growth.—George Emerson Brewer reports these cases. The first patient was a boy of eleven years. When five years of age he suffered from extensive papillomatous disease of the larynx, which interfered considerably with his respiration. The condition grew worse, till, on account of the extreme dyspnea, it was necessary to perform an emergency tracheotomy. By persistent local treatment the greater part of the laryngeal growth was removed, but while it left a sufficient opening in the glottis for ordinary respiration, no relief was afforded. As soon as the tube was removed the dyspnea was grave. An obstruction in the trachea, immediately above the opening for the canula, was evident. At operation there was found, immediately, above the old tracheal opening, a large papillomatous mass, completely plugging its lumen, and attached by a comparatively small pedicle to the left side of the trachea. It was about the size of a large blackberry. It was easily removed. Several papillomatous masses on and below the vocal cords were also removed. The greatest precautions were taken on account of the anemic condition of the boy, to avoid the dangers incident to such an operation. The entire larynx and the cervical part of the trachea were laid open, affording a clear view of the entire extent of the disease. The use of cocaine and adrenalin on the mucous membrane served to avoid the rapid fall of blood pressure and consequent symptoms of grave shock, and also produced a marked anemia of the tissues, preventing extensive oozing. Chloroform was used, and the patient put into the Trendelenburg position. The second patient was a physician suffering with adenocarcinoma of an accessory thyroid gland. The growth caused marked tracheal stenosis. Dyspnea at last became so alarming that immediate operation was decided upon. Chloroform was administered. The patient took it well till the position of the head was changed to allow the performance of a preliminary tracheotomy. The dyspnea then became extreme and an alarming degree of cyanosis developed. An incision in the median line was made from the cricoid to the suprasternal notch, and thence was continued down toward the right in a curved direction for about three inches. While the trachea was being exposed the patient ceased to breathe and the skin became livid. The cut surface of the thyroid bled profusely, but as soon as the hemorrhage was controlled the trachea was opened and a tube was introduced. Respiration was re-established. There was a large encapsulated tumor beneath the thyroid gland, partly within and partly above the mediastinum. This growth was removed. The patient's recovery was prompt and practically uneventful. The tumor proved to be an adenoma, probably of an accessory thyroid. In it there were slight changes suggesting carcinomatous degeneration.

American Medicine, February 11, 1905.

Some Forms of Insanity Due to Alcohol, Especially in Their Medicolegal Relations.—Chas. K. Mills briefly discusses the different forms of acute and chronic alcoholic insanity with medicolegal bearings; these including, although in relative degree, almost all types of alcoholic mental disorder. The alcoholic somnambulist may steal or kill in his abnormal sleep; the alcoholic melancholiac may commit suicide or destroy others because of his depressive delusions. The alcoholic suffering from acute mania may strike down his fellowman in his wild excitement. The victim of delirium tremens, in trying to defend himself from his tormenting hallucinations and delusions, may do great harm to others and to himself, and the alcoholic dement may be unfit to care for himself or his estate, and therefore may need the protection of the law. Chronic persecutory insanity, or alcoholic paranoia, and dipsomania are especially considered. Special stress is laid upon the fact that in the former the delusion of marital infidelity plays a leading rôle; it may be associated with delusions of poisoning, with hallucinations of sight or hearing, or it may be the only evidence of insanity and very difficult to demonstrate. Mills classes dipsomania with the impulsive insanities. He emphasizes the distinction between dipsomania and inebriety with periods of great excess, and also between dipsomania and other forms of alcoholism.

Subcutaneous Alimentation.—Arthur E. Barker gives the results of several years' personal experience in surgical cases with infusions, both subcutaneous and intravenous, of physiological saline solution and of glucose, the latter being added as a food. The advantages of saline infusion consist (*a*) in the introduction of water, which is often badly needed by the tissues, (*b*) in the dilution of toxins, and (*c*) in the increase of elimination. One special effect of the loss of water in the tissues under certain pathological conditions is the irritability of the nerve centers, requiring only some accidental stimulus to call forth explosive action. Barker prefers this to the theory of intoxication through absorption of some fermentative product. It is possible that subcutaneous injections of a half liter of saline solution with glucose produce or encourage leucocytosis and phagocytosis. Saline solution may be made the means of conveying oxygen to the blood directly, and so stimulating the heart in cases of shock. The method is to shake up with the warm saline solution about one-tenth of its volume of pure oxygen, and introduce this by puncture into a vein. Subcutaneous infusion would not answer. Oxygen is also administered by the lungs at the same time. So far it has only been a question of supplying water to the tissues safely, the sodium chloride being meerly added to make an isotonic solution. It is desirable at times to do more than introduce water. Often the rectum is unavailable for alimentation, or it is necessary to supply food more rapidly than is possible by the rectum. Barker has for many years employed pure glucose for this purpose. A 5 per cent. solution in distilled water has a freezing point of 0.56° C., isotonic with the blood. It is well not to trust the sterility of such solutions too long. They should be injected at about blood heat, otherwise they cause pain. In some cases the effects are very remarkable, and in no case could any injury be traced to the injection, when used either to prepare a patient for operation or to combat the exhaustion following the operation. Barker has had only a limited experience of the subcutaneous injection of olive oil, and is not prepared to speak definitely concerning it.

Typhoid Coxitis.—John L. Porter briefly reviews the literature and reports a case of typhoid infection of both hips in a boy of 10. The points of interest in the case are: (1) Both hips were involved; (2) infection occurred with acute symptoms during convalescence; (3) one joint, which broke open and discharged, recovered with almost normal motion and no destruction, while the one that did not rupture underwent extensive destruction and spontaneous dislocation, with extreme flexion deformity. The dislocated joint was reduced by tenotomy and forcible correction, resulting in shortening of one inch, fair mobility in all directions except flexion, a good standing position, and the ability to walk and run without support.

Journal of the American Medical Association, Feb. 11, 1905.

Chorea.—W. G. Spiller thinks that the relation of chorea to rheumatism has been greatly overestimated. In most of his cases he could not detect it. He also has not been able to recognize any peculiar facies of the disease, nor does he agree with Gordon and Eshner that there is any peculiar characteristic of the patella reflex in chorea. The arsenical treatment of the disease does not seem to be without disadvantages, and should be watched very closely. He has seen arsenical neuritis and idiosyncrasy. The pathology of the disorder is still obscure. The "chorea bodies" are not characteristic. Apoplectic hemihypertonia is distinct from athetosis; the spasm is tonic, unilateral, associated with a little weakness, but not with contractures, develops after an apoplectic attack, and is probably due to irritation of the motor fibers below the cortex. Spiller does not accept Kahler and Pick's theory of the choreiform movements being caused by irritation of the pyramidal tract. It is hard to understand the comparative rarity of hemichorea if this were the case.

Convulsive Tic.—According to H. T. Patrick, convulsive tic may be said to be a habit spasm, a sort of motor expression of an imperative impulse. It may develop from some peculiar motion incident to the patient's occupation, but its original cause is generally sensory—some uncomfortable sensation which an attempt is made to relieve by a movement which finally becomes habitual. It does not affect voluntary movements, is diminished by quiet, rest or mental diversion, and is aggravated by self-consciousness, observation, excitement, etc. The prognosis varies. In children it is ordinarily good, but in adults it is often rebellious. The patients are generally nervous and unstable, and, in cases of children, unwise parents and rearing are often responsible. With them the habit may be broken by judicious diversion or correction. With adults, the treatment is apt to be unsatisfactory, but Patrick thinks the soporific treatment, keeping the patient asleep for two or three weeks at a time, using hypnotics judiciously, with frequent changes of the drug, followed by the educational exercises of Brissaud, will be found most effective in the spasmodic torticollis of the adult.

Hysterical Movements.—H. T. Pershing gives the diagnostic points of hysterical movements, as compared with chorea and convulsive tic. One characteristic is that they are always movements which can be produced voluntarily, though this also may be the case with convulsions from organic disease. The more regular the movement, the greater the probability that it is hysterical, but the possibility of hysteria complicating other conditions must not be forgotten. The most characteristic movement is a

rhythmic oscillation involving one part, and next are certain highly co-ordinated movements, such as jumping or dancing, with or without impairment of consciousness. Chorea may simulate hysteria and be due to similar emotional causes, and the diagnosis may be difficult. Hysterical movements are more likely to be regular and grouped in distinct paroxysms, and to have more of the staccato movement, but most of the rules for distinguishing these diseases require qualification. Hysterical movements of a limb may simulate Jacksonian epilepsy, but there is no rise of temperature, no paralysis nor mental deterioration. Prognosis and treatment must be guided by general principles. A cure is always possible, though the condition may be obstinate. Moral treatment is imperative. If the patient's mental processes can not be happily directed, everything else will be useless. If they are so directed, the rest will be easy.

Blank Cartridge Tetanus.—D. H. Dolley has investigated blank cartridges from several makers with special reference to their bacteriological contents, employing cultural and incubation, as well as microscopical methods. The findings were rather negative as regards the tetanus bacillus, but the *Bacillus aërogenes capsulatus* (Welch) was present in a large proportion of the cartridges examined. Notwithstanding this fact, tetanic symptoms developed in a number of the animals inoculated, and in still other animals inoculated with cultures from these. His conclusions are: 1. *B. aërogenes capsulatus* (Welch) is present in a large proportion of the wads of the three makes of the cartridges examined. 2. The wads of one make, inoculated in rats, guinea pigs, and rabbits, produced characteristic symptoms of tetanus. 3. The powder of the three varieties of cartridges examined was negative for *B. tetani* and *B. aërogenes capsulatus*. 4. Efforts at isolation of *B. tetani* from the wads have so far been unsuccessful. 5. There is abundant evidence, however, from clinical observations and animal experiments, that the wads of certain blank cartridges contain *B. tetani*.

The Lancet, January 28, 1905.

Myelopathic Albumosuria.—C. W. Piget Moffatt, in describing this disease, says that it is one about which the average medical man knows very little. He appends records of 39 cases which he has found in the literature. Bence Jones was the first to call attention to this disease. The symptoms found in every case are pains in the back and sides. Weakness and anemia are progressive, and though there may be a remission of the acute symptoms, for a time, they always recur and progress to a fatal ending. In many cases, spontaneous fractures of the ribs have occurred, and in many also, there have been noted tumors growing from the ribs, and deformity of the lumbar and dorsal vertebra. Nothing is known concerning the etiology of the disease. Of two cases seen by Bradshaw, one had a gumma of the tongue, and the other gave a history of syphilis. But notwithstanding this fact, there is no reason so far as is known for associating the two diseases. The prognosis is absolutely bad. In only a few of the cases on record, has life been prolonged for more than a year after the patient has consulted a physician. It is said, however, that in Kahler's cases, some symptoms were present eight years before death. The end may come from exhaustion or from some intercurrent disorder, of which pneumonia appears to be the most frequent. There is no known efficient treatment. The drugs that have been used seem to have absolutely no effect in influencing the course of the disease. In the differential diagnosis of myelopathic albumosuria, the following diseases must be thought of: Osteomalacia, muscular rheumatism, lumbago, sciatica, and so on, spondylitis deformans, caries of the spinal column, invasion of the vertebral column, and other bones by secondary malignant tumors, pernicious anemia or other diseases associated with progressive cachexia, nephritis, and chyluria. The pathological changes are almost all confined to the skeleton. The ribs, the sternum and vertebra always seem to be affected, and in certain cases the skull and pelvic bones. The new growth is gelatinous, soft and vascular. Sometimes it is confined to the interior of the bone, while in other instances it bursts through the compact tissue, and forms tumors of considerable size. This growth is composed of round cells with little or no intercellular substance. Fat globules are often noted in the cells, and now and then cells of a higher type are seen. Spindle cells are sometimes present. In its structure and clinical progress, there is a strong resemblance between this growth and sarcoma, but it differs from the common forms of sarcoma "in its invasion of several parts of the skeleton simultaneously, and in its showing no tendency to form metastases in other parts or organs." Besides the presence of Bence Jones proteid, there is no constant peculiarity in the urine. As to the blood, nothing beyond simple anemia seems to have been determined. There is no record of the presence either of myelocytes or nucleated red corpuscles. Interstitial nephritis has been found in some cases. In other cases the kidneys were normal. There seems to be no necessary association between this disease and pathological changes in the kidneys. The writer then gives a careful description of a case of this nature which he has had the opportunity of observing.

The Presence of Plasmodiophoræ in Carcinomatous Tumors and the Successful Culture of the Parasites.—W. Ford Robertson and Henry Wade have been studying carcinomata especially with a view to testing the validity of the hypothesis that these growths are dependent upon the growth of a parasite of the same class as the plasmodiophora brassicæ, which is known to cause tumor growths in certain plants. They have used the silver method in staining, toning the silvered sections with gold, platinum, and palladium. They have traced what appear to be three parallel lines—those of the life-cycle of the plasmodiophora brassicæ, a series of bodies found especially within the cells of carcinomata, and the stages of an organism which can be grown from such tumors. Although the last line is incomplete, still through eight successive phases, or four separate stages, the parallelism is exact. They affirm that all the stages of a plasmodiophora are accurately represented in carcinomata, and it has been impossible to construct a similar series from control tissues. Several distinctive morphological features have been observed in the supposed parasites. As to the study of cultures, in the sections of the growths in agar, tissue cells are absent, and there is present an organism which has obviously been multiplying rapidly. At least in one instance this organism has been found in four distinct forms, which exactly harmonize with four successive stages in the developmental cycle of the plasmodiophora brassicæ, as well as with that which has been found in sections of carcinomata. The writers conclude that, if further researches confirm their results, the etiological relationship of the plasmodiophoræ to carcinomata will hardly require further proof, and if a protozoan organism of this nature is the essential etiological factor in carcinomata, antibodies will doubtless be produced, by the therapeutic use of which the body will become able to overcome the parasites in such growths.

Relation between Various Atmospheric Conditions and the Occurrence of Cerebral Hemorrhage.—James W. Russell presents the following conclusions: There seems to be a slight tendency towards the occurrence of cerebral hemorrhage on days of high atmospheric pressure, and also on days of rising pressure, the former being probably the important factor. There is a very marked tendency on days of low wind pressure, and the combination of a low wind pressure with a high barometric pressure is the condition under which the largest number of cases took place. Apart from season, temperature in itself has not been shown to exert any influence, though a small excess of cases has been noted on days with a rising thermometer, and also with a combined rise of atmospheric pressure and temperature.

A Case of Severe Cough and Loss of Weight Due to Round Worms in the Intestine.—Prosper St. Leger Liston describes the illness of a boy, aged thirteen, who measured 4 feet 11 inches in height, and weighed 36 pounds. When the writer saw him he was suffering from an intense earache. He had had cough, expectoration, and night sweats. The expectoration was often bloodstained, and he was supposed to have "consumption." He was extremely emaciated. His temperature was 104° F. His abdomen was greatly distended and painful. Diarrhea was present; there was no appetite, and the boy rarely had more than an hour's rest at night. Two sisters had died from some vague stomach trouble. When the writer examined the patient's throat, he found an intestinal worm, with its head firmly wedged into the Eustachian opening. It was pulled away with great difficulty, after which the boy experienced great relief. Santonin, calomel, and scammony were prescribed, and at the end of a fortnight he voided, either by vomiting or per rectum, 603 round worms, varying in length from 4 to 9 inches. The cough has disappeared, he has gained 14 pounds in weight, and his appetite has returned.

British Medical Journal, January 28, 1905.

Tuberculous Synovitis Treated by the Röntgen Rays.—A. Gregor reports the case of a boy of seventeen years, who for the eighteen months previous to the author's first examination had gradually been growing worse. The left knee joint was the one involved. Two *x*-ray exposures were made for purely diagnostic purposes, but the patient reported soon after that since the exposures to the rays the pain and swelling in the joint had lessened, and he wished to have the rays applied again. This was done by the author, who used a coil with a 14-inch spark. The focus tube was of high resistance. The distance from the wall of the tube to the affected part was 6 in. The amount of current used was 6 ampères, at a pressure of 60 volts. The duration of the sittings was ten minutes twice a week. In all, eleven exposures were given, including the two preliminary ones for diagnostic purposes. The pain and

swelling rapidly subsided, and the joint became absolutely normal, and has remained quite well ever since.

Nasal Disease as a Cause of Headache.—A. L. Whitehead considers the following facts as definitely established: (1) Nasal disease is undoubtedly the cause of headaches in a certain percentage of cases, although it is doubtful whether it is possible for headache to be produced by any nasal condition which does not give rise to discharge or to obstruction to normal nasal respiration. (2) In all cases of persistent headache, a careful examination of the nose should be as much a routine practice as the examination of the urine, the teeth, and the eyes; since in some instances the nasal symptoms may be ignored by the patient, and a careful examination of the nose will be necessary to establish the diagnosis. (3) Suppuration in the accessory sinuses and marked nasal obstruction, constant or intermittent, should be thoroughly treated. (4) Small spurs, deviations, and hypertrophies not causing obstruction should be left alone, as no relief will be given from the headaches by treatment of these. (5) If the middle turbinate bones are enlarged and pressing upon the septum, especially upon the tubercle, and if all other possible causes of headache have been eliminated, partial removal of the hypertrophied bone should be advised, since in many such instances complete relief is given.

Suppurative Frontal Sinusitis.—The surgical treatment of this condition by W. Milligan, on the basis of his personal experience with forty cases. In the majority of these the factors which have mainly decided the question in favor of external operation have been (1) the failure of intranasal treatment, (2) persistent purulent disch[illegible], (3) severe attacks of headache, and (4) general mental hebetude. The author says that, if by "cure" we mean entire absence of pus, cessation of headache, complete healing of the primary brow incision and avoidance of diplopia, the percentage of recoveries is not particularly great. But after opening and draining the pus cavities there is a vast improvement, even though a little [illegible] may appear now and then in the nares. The main practical difficulties encountered in treatment are (1) the efficient removal of all disease, (2) the maintenance of free drainage, and (3) the avoidance of secondary infection. The author goes into details of operative technique, and says that of his forty cases, two died from abscess within the corresponding frontal lobe. In both cases the abscess was complicated with septic meningitis. Twenty-eight of the patients, or 70 per cent., made a complete recovery and have had no recurrence of suppuration. Four of the patients, or 10 per cent., have still a discharge, although small in amount, from the sinus. In five of the cases, or 12.5 per cent., despite fairly persistent treatment, in two of the cases, extending over a period of four years, fairly profuse suppuration still persists from both frontal and both ethmoidal sinuses. In one case the result is unknown. A good result is not anticipated, the patient having developed pulmonary tuberculosis. The intricate arrangement of the accessory nasal sinuses, the difficulty encountered in securing at any one operation a complete eradication of disease, of maintaining free drainage, and the risks of reinfection are factors which militate in no small measure against a successful issue.

Berliner klinische Wochenschrift, January 23, 1905.

The Cure of Exophthalmos and Chorea by the Removal of Adenoid Vegetations.—[illegible] Moebius, and other authors in believing that exophthal[illegible]ne, if not due to mechanical causes, is sufficient ground [illegible] making the diagnosis of Basedow's disease. He describes two cases of exophthalmos which were completely relieved by removal of adenoid vegetations. The first case was that of a boy of seven years, with well marked exophthalmos, accompanied by both Graefe's and Stellw[illegible] signs, and who further presented the clinical picture t[illegible] of adenoids. Ten days after removal of the pharyn[illegible] tonsil the exophthalmos had completely disappeared. [illegible] years later the patient reappeared with a return of all his [illegible] [illegible]panied by bilateral exophthalmos. Radical extirpation [illegible] ocular protrusion. The second patient was also a boy [illegible] in addition to adenoids and exophthalmos, suffered from hypertrophy of the tonsils. Amputation of the latter structures was not followed by improvement in the exophthalmos, but a week later the [illegible]noids were removed, and in the course of the [illegible] two weeks the exophthalmos disappeared completely. The author is of the opinion that Basedow's disease repr[illegible] an intoxication of the central nervous system through abnormal internal secretions, and that adenoid vegetations are capable of evoking the malady. Epilepsy and chorea probably have some etiological similarity to Basedow's disease, and the author thinks that they also may be produced by the presence of adenoids. An illustrative case is cited in which clearing of the nasal pharyngeal space in a boy of seven years was followed by the cure of a well marked chorea minor. It therefore appears advisable to look for adenoids in all cases of these three diseases, and to remove them, even if there is no respiratory obstruction.

Camphor and Digitalis.—Maas says that although camphor and digitalis are usually mentioned in the same breath by the clinician, the manner of their action on the heart is totally different, and the only similarity they possess from the physiological standpoint is their regulatory action on the circulation. Although camphor has been employed as a medicament since very early times, and has been made the subject of many investigations, its mode of action is still more or less obscure. Recent work by Winterberg on the isolated heart and on the organ *in situ* seems to show that the drug has but little effect on the normal heart, and that its clinical value lies in the more favorable circulatory condition attending the well marked vascular dilatation it produces. Seligman's experiments on the Langendorff heart, that is an isolated, warm blooded heart kept in activity by artificial coronary circulation, show more direct action of the drug when the organ approaches exhaustion. As this stage is reached a condition of fluttering appears, after which it is usually impossible to produce regular contractions again, but if camphor be introduced into the circulation, the former activity is promptly restored. By the application of electricity it is possible to produce fluttering in an unfatigued heart, but not if camphor is present in the artificial circulation. The action of digitalis is complex, but has been much more precisely outlined, and now the properties of the various constituents of the drug are being studied. Digitoxin is more of a vasoconstrictor than digitalin, and is slower to produce its effects, while elimination is also delayed, so that there is greater danger from cumulative poisoning. The therapeutic and toxic doses of digitoxin are very close together, and it is impossible to slow the pulse by a single dose of this constituent without killing the animal.

The Intravenous Injection of Salicylates and Its Diagnostic Value.—Mendel urges the employment of intravenous injections of salicylates in rheumatic affections, because this method of application is the quickest, and most reliable for removing pain and fluid exudates in joints, especially in afebrile cases, because it is effectual in cases where the usual treatment fails, and because it is free from the disagreeable by-effects often accompanying the internal administration of the salicylates. The solution used consists of sodium salicylate, 8.75 gr., caffein 1.25 gr., and distilled water to make 50 c.c. It is imperative that the solution be fresh and absolutely sterile. The technic of injection must also be carefully carried out. After boiling the needle, and washing out the syringe with boiling water the solution is drawn into the syringe. The veins of the anterior aspect of the elbow are then congested by applying an elastic bandage to the upper arm, and the most prominent one is chosen. The skin is cleansed with ether, and the needle pushed flatwise into the vessel. The column of blood rising into the syringe is an indication that the vein has been entered, and the injection, consisting of 2-4 c.c. is completed. The elastic ligature is not removed until after the needle is taken out of the vein, in order to avoid all danger of air embolism. One of the most important advantages of the method lies in its diagnostic value, for if prompt relief to pain and swelling do not follow a single injection, it may safely be assumed that the affection is nonrheumatic in character. The author quotes numerous cases in which the differential diagnosis between rheumatic, gonorrheal, tuberculous, and other joint diseases was cleared up by the injections. When carefully carried out he says there is no danger from the injections, as is attested by the fact that he has made over 8,000 without any bad effects.

The X-Ray Treatment of Leukemia.—Wendel has collected from the literature thirty-eight cases of leukemia treated by the *x*-ray, and has tabulated twenty-seven of them so as to show the chief features of interest in each instance. He [illegible] improvement followed the use of the rays, so that the patient who had been in a critical condition when coming under observation, was enabled to return to work, and the leucocytes dropped from 56,000 to 16,000. Omission of the treatment for any length of time, gave rise to relapses which, however, promptly succumbed to further radiotherapy. It appears that in 90 per cent. of the reported cases the use of the rays had been of signal benefit, but it is still uncertain whether actual cures are produced.

Münchener medizinische Wochenschrift, January 24, 1905.

Formalin Onychia and Dermatitis.—Galewsky says that the applications of formalin in the industries and arts have become so numerous that the yearly product of the agent is in the neighborhood of 400,000 kg. In consequence of this extensive use, it is not surprising that cases of injury to the skin of those who work with the substance are reported.

Slight degrees of dermatitis are frequently observed among patients who habitually use formalin soaps, etc., for the purpose of checking hyperidrosis, but the author describes a more severe type of lesion affecting the nails also, of which he has seen five cases. The condition followed the protracted use of 4 to 10 per cent. formalin solutions, and three of the patients were physicians, who were exposed in the course of pathological work, one was the attendant in a pathological laboratory, and one was a druggist. The effects were not visible until after six to nine months' work with the solutions, and began with a brownish discoloration of the nails. The nails soon became soft and very brittle, so that they frayed out into shreds, at the same time causing severe pain by the irritation of the swollen matrix and adjoining tissues. In two of the cases the nails alone were involved, but in the others the fingers and hands were also the seat of an eczematous inflammation. The affection was extremely obstinate, lasting from three-quarters to one and a half years before normal conditions were restored, and in one case leaving behind a susceptibility to irritation by all other chemical solutions. The treatment consists in avoiding contact with the formalin and in the use of the remedies customarily employed in eczema.

French and Italian Journals.

The Röntgen Rays in the Treatment of Cancer.—Djemil Pacha after briefly reviewing the history of this subject, reports seven cases of malignant growth, six of which were carcinomata and one sarcoma. Three of these cases were cured by means of the Röntgen rays, three were improved, while in one case this treatment was not successful. There were four cancers of the breast, one sarcoma of the breast, one epithelioma of the nose, and one cancer of the stomach. In four of the cases, the disease was far advanced, while in the other three it was more recent. Of the cases that recovered, two were cancers of the breast, the other, epithelioma of the nose. All three were recent. It is now five months since the recovery of these patients, and there has been no appearance of recurrence. Of the cases in which improvement, but not recovery followed the treatment, two were cancers of the breast, already operated upon but with recurrences, and the third was cancer of the stomach. In the first, two, after several sittings, these patients suffered no more the excruciating pain to which they had formerly been subject; their wounds which had been freely suppurating, and which were most offensive, were completely cicatrized; and appetite returned. In the case of cancer of the stomach, the growth was the size of a child's head. Operation revealed extensive adhesions, and it was found impossible to practise gastroenterostomy. Treatment by the Röntgen rays gave great relief, and the patient died without pain, two months after the operation. The results of this treatment in the case of the sarcoma of the breast, were nil. The writer inclines to the parasitic theory of cancer, and thus thinks that the *x*-rays have a parasiticidal action. In his experience, radiotherapy has apparently had a very favorable action on malignant tumors in general. In superficial cancers not far advanced, radiotherapy has resulted in recovery, as far as can now be told. Time alone will prove the ultimate results. Radiotherapy is a palliative treatment in deep cancers of advanced stage, and exerts a salutary influence over cachexia. In inoperable malignant tumors, with no chance of surgical intervention, radiotherapy is most valuable in offering a means of reducing the sufferings of the patients to the minimum.—*Revue de Chirurgie,* January, 1905.

Toxicity of Boric Acid.—According to Chevalier, intoxications not infrequently develop after repeated doses of boric acid during several days. Generally, such accidents occur at the end of the third or fourth day, that is, when the organism is saturated with the acid by its accumulation, by its non-elimination, or by its faulty elimination. If this drug can be employed continuously without bad effects in many cases, it is because of its difficulty of absorption, and the ease of its elimination, in the normal state. But when it is absorbed in a considerable quantity, and when its elimination is interfered with, toxic phenomena are sure to occur. Those really serious or fatal accidents are always due to the employment of this medicament in the form of powder for the dressing of wounds. The symptoms are quite variable: Sometimes cutaneous eruptions appear; again, symptoms related to the digestive or to the nervous system are the most alarming. Rarely cardiac complications occur. The writer is confident from his researches, that boric acid is not harmless when it is absorbed, and especially when it is retained. It is important to watch carefully the effects in patients suffering from renal insufficiency, and it may be dangerous to use it internally, for a long time, or in the form of powder, in dressings for wounds.—*Revue Française de Médecine et de Chirurgie,* January 9, 1905.

Blood Stains in Pernicious Anemia.—J. Sabrazès calls attention to the interesting work of Tallquist on this subject. When a drop of blood spreads out on a piece of absorbent paper, and is surrounded by a ring of watery aspect, it indicates a very marked anemic condition—a loss of at least half of the normal number of red blood corpuscles—and this phenomenon leads one to think most often of pernicious anemia. In chlorosis, even the palest, this phenomenon does not take place. The writer has also verified the importance of this experiment in the diagnosis of anemias. He has also made further observations in a case of pernicious anemia: The blood stain is more red at the periphery than in the center; the watery line that surrounds it, very clear when it is fresh, is not less clear when the stain is dry, it persists a long time after the paper has been wet; this line has a slightly oily appearance; the color of this watery line varies from a dull white to clear yellow, and shows the tint of the plasma which is sometimes relatively deeply colored in pernicious anemia. On red litmus paper, the blood stain gives a reaction far more blue at the aqueous peripheral line.—*Gazette Hebdomadaire des Sciences Médicales,* January 8, 1905.

Healing of Cartilage in Wounds.—G. Faseli, in order to establish the method of healing of cartilage, experimented on rabbits. One series of experiments dealt with aseptic wounds of the cartilage covering the condyles of the femurs. The elements nearest the wound became atrophied; the basement substance was partially reabsorbed, and substituted by a new substance elaborated by the cells; small wounds cicatrized perfectly through the activity of the original cartilage cells; these were recognizable by a zone of tissue poor in cells; the new basement substance formed was exuberant in its growth; a large wound was not entirely repaired; no cartilage formed, but the deficiency was filled by the connective tissue; if the wound extended into the bone, the medullar elements filled the wound, forming a kind of callus; if the wound was very extensive, repair did not go on, but atrophy occurred. A second series of experiments dealt with the elastic cartilage of the rabbit's ear. The cartilage cells did not undergo changes; the basement substance remained unchanged, but a callus repaired the breach, arising from the perichondrium and the surrounding tissues, which underwent proliferation; if two wounds were made, each underwent repair separately. If too great removal of tissue occurred, connective tissue filled the wound; the smaller the wound, the better repair went on.—*La Riforma Medica,* January 14, 1905.

Relation between Thyroid and Pancreas.—Alfonso Pirera experimented on dogs, producing hyperthyroidism, extirpation of the thyroid, and removal of the pancreas, then examining the organs histologically. His conclusions are as follows: (1) In dogs injected with thyroid substance, so as to be hyperthyroidized, there were destructive lesions in the islands of Langerhaus in the pancreas. (2) In dogs deprived of a thyroid, lesions of the pancreas were not constant. (3) The lesions indicated an essential nervous mechanism for the pancreas. (4) In dogs without any pancreas, the thyroid showed hypersecretion and increased function. (5) These alterations may be the cause of the manifestation of symptoms of Basedow's disease in diabetes. (6) Occasionally there was irritation and atrophy of the gland. (7) A relation between the thyroid and pancreas may be considered demonstrated, and a vicarious action of one for the other.—*Giornale Internazionale delle Scienze Mediche.* January 15, 1905.

Idiopathic Multiple Hemorrhagic Sarcoma of the Skin.—Francesco Radaeli gives us five cases of this disease observed by him, that were treated by the use of arsenic, and in all of which portions of the tissues affected were removed and carefully examined. The symptoms consisted of the appearance of patches of infiltration on the extremities, accompanied by pain and, after a time, by cachectic condition. One case died with a cachexia like that of malignant disease. The other cases were treated with arseniate, and cacodylate of soda, and he believes them to have been benefited generally, as well as to have shown a resolution of many of the affected patches, although the formation of new patches was not prevented. As to the histological findings, he distinguishes insipient from advanced patches; in the former there was produced a tissue full of new vessels and consisting of elongated cells with round or oval nuclei, similar to endothelial cells; that is, a true hemoangioendothelioma. The skin about these patches was the seat of a diffuse infiltration with thickening of the vessel walls; stasis and edema of the connective tissue occurred; and pigmentation, due to masses of changed red blood corpuscles. There were also patches of infiltration of small round cells about the vessels. The author believes the process to be a fibroplastic infiltration. In adult forms there were produced true tumors, arising from the infiltrated patches, and in structure not differing from the neoplastic infiltration already described. The author believes that in some of his cases a true resolution occurred in some of the patches. Cultures were made with the result of finding no microorganisms.—*Lo Sperimentale,* December, 1904.

Book Reviews.

Poverty. By Robert Hunter. New York: The Macmillan Company, 1904.

One puts down this intensely interesting book with a feeling almost of despair, so hopeless seems to be the struggle of the poor against inexorable fate, so impossible does it seem to be for them to rise above the level of actual or ever-threatening want, so invincible seems to be the ultimate merging of poverty into pauperism and vagrancy. Yet the book, with all its pessimism, is one of great value to the philanthropic and the would-be practical sociologist, for in it Mr. Hunter shows very clearly what among the alleged remedies are useless and what are harmful, and, though the author says little regarding the prophylaxis or cure of the ills he so graphically describes, his few suggestions have the merit of practicability, and at least contain the germs of what may be developed into something really remediable. The main objects of the work, Mr. Hunter tells us, are to define poverty and to estimate its extent in this country; to describe its evils and to point out the measures possible to be taken to remedy the same; and (here lies the pessimism and the note of despair) "to show that the evils of poverty are not barren, but procreative, and that the workers in poverty are, in spite of themselves, giving to the world a litter of miserables, whose degeneracy is so stubborn and fixed that reclamation is almost impossible, especially when the only process of reclamation must consist in trying to force the pauper, vagrant, and weakling back into that struggle with poverty which is all of the time defeating stronger and better natures than theirs." The book is not a scientific treatise, bristling with statistics, but rather (and herein lies its fascination for the layman and the amateur sociologist) a narrative of what the author has seen and heard and felt while himself living among the poorest of the working people and even among the scum and offscourings of society in this and other countries. No one with the power of pity in his heart, and with a longing, however vague, to help his fellows, can read this book without having his longing intensified to the point of action.

Clinical Hematology. A Practical Guide to the Examination of the Blood, with Reference to Diagnosis. By John C. DaCosta, Jr., M.D., Demonstrator of Clinical Medicine, Jefferson Medical College; Chief of Medical Clinic, and Assistant Visiting Physician, Philadelphia General Hospital; etc. Second Edition. Revised and Enlarged. Containing nine full-page colored plates, three charts, and sixty-four other illustrations. Philadelphia: P. Blakiston's Son & Company, 1905.

The second edition of this book is well designed to maintain the favorable impression produced by its predecessor. The fabric of this department of medical knowledge is undergoing such a rapid growth and modification that in order to keep each successive appearance of a volume on the subject vital and practically useful, unremitting labor is required on the part of the author. That the present work has been subjected to careful revision is evident from a glance at the table of contents, which includes many new topics. The science has grown in all its branches; new diseases have been added to the list of those depending primarily on disorders of the blood, and more or less important blood changes have been discovered in [illegible] already known, while improvements in technique include many different staining and other methods, and new apparatus. Perfection is difficult of attainment, and even in this book, excellent as it is, it would not be difficult to select numerous points for criticism, but the general tenor of the volume is so satisfactory that it is a pleasure to commend it to those interested.

The Surgery of the Diseases of the Appendix Vermiformis and Their Complications. By Drs W. H. Battle and E. M. Corner of London. Chicago: W. T. Keener & Company, 1905.

This is a book which aims to present a concise review of present-day knowledge of this most important subject, with especial reference to the surgical aspects of the disease. In addition to the etiology, pathology, and treatment, several chapters [illegible] including one to the subject of the relation of appendicitis to life insurance. The chapters on etiology and pathology present merely a compendium of accepted facts. In the discussion of the various operative procedures, the method of opening the abdominal cavity, first introduced by the senior author, is advocated in preference to that of McBurney. It consists of a vertical incision to one side of the median line, with temporary displacement of the rectus muscle. In all their cases, only one hernia resulted after operation, and that was in a case of extensive local suppuration. For amputating the appendix, a special form of clamp is recommended, which crushes both the mucous and muscular coats, and the remaining thinned out serous coat is then tied with silk close to the cecum. There is a great deal of interesting information gathered in this book, which makes it valuable as a work of ready reference.

Manual of Practical Ophthalmology. By George A. Berry, M.B., F.R.C.S., Ed., Senior Ophthalmic Surgeon, Royal Infirmary; Surgeon Edinburgh Eye Dispensary; Ophthalmic Surgeon Royal Hospital for Sick Children; Lecturer on Opthalmology University of Edinburgh. Philadelphia: J. B. Lippincott Company, 1905.

The author has given us a manual intended largely for the training of the general practitioner in practical ophthalmology. In his preface he admits the large number of works on the eye already existing, but wishes his readers to approve of still another work on the same subject. There are over five hundred illustrations, most of which are original, and in most instances they portray clearly the subject in hand. The author refers to the latest mode of treatment under the proper headings, but, as a rule, sanctions those only of a mild and conservative nature. The book contains a full table of contents, list of illustrations, and a well-arranged index.

Die angeborene Pylorusstenose in Saüglingsalter. Von Dr. Jussuf Ibrahim. Berlin: S. Karger, 1905.

This is a monograph based on the author's personal observations in three cases which he was able to follow very closely, day by day. The prognosis is considered doubtful by some authors and relatively good by others. The question depends largely on intelligent interpretation of the clinical symptoms and a rational internal treatment should always be tried before operative interference is advocated. The indications for operation may be stated as follows: pyloroplasty or distention in those cases in which the emaciated condition of the patient necessitates rapidity of operative attack and a brief narcosis; when the general condition is better, gastroenterostomy is preferable. The work forms a valuable contribution to the literature of the subject.

Diseases of the Lungs, Bronchi, and Pleura. By H. Worthington Paige, M. D., Lecturer on Theory and Practice of Medicine in the New York Homeopathic Medical College and Hospital; Member of the Attending Staff to the Flower Hospital, the Hahnemann Hospital, and the Laura Franklin Free Hospital for Children; Late Assistant Surgeon to the Throat Department of the New York Ophthalmic Hospital. Philadelphia: Boericke & Tafel, 1904.

The author has prepared this little volume to serve as a text-book on the subjects treated. Essential facts are practically told and unproved theories are not discussed. The five sections treat of diseases of the trachea, bronchi, lungs, pleura, and medidastinum. In his remarks on treatment, the author has limited himself to those remedies which have been found to be most frequently useful to the homeopathic practitioner. The book is supplied with a convenient index.

Electricité Médicale. Par Le Docteur H. Guilleminot. Avec 79 Figures dans le Texte et 8 Planches hors Texte. Paris: G. Steinheil, 1905.

The text of this volume is presented in three parts. In the first section are arranged the theoretical and technical teachings in relation to galvanic and faradic currents, currents of high frequency, static electricity, the *x*-ray, seismotherapy, mechanotherapy, phototherapy, thermotherapy, and so on. The second section is devoted to the study of the physiological effects of different forms of electrical energy, while in the third division is found the medical material, properly speaking. Each disease is the subject of a special paragraph in which are grouped the indications for technique of all interventions which are considered useful in that particular instance. The work will prove helpful to both student and practitioner, for it combines in one volume material which heretofore the reader has generally been obliged to glean from several sources.

One Hundred Years of Publishing (1804-1904). A Brief Historical Account of the House of William Wood & Company. New York: William Wood & Company, 1904.

This little brochure contains a brief historical account of the foundation and growth of the medical publishing house of William Wood & Company. The modest beginnings were made in 1894, Samuel Wood, a schoolteacher of Long Island, coming to New York and opening a little shop for the sale of books and stationery. His pedagogical instincts led him soon to begin the publication of primers and other booklets for the instruction of the young, and from this the work branched out into the publishing of more serious books of instruction, several of which are still on the firm's list, and finally of medical books. It is interesting to note that there is but one older publishing house in New York, and no medical book publishing house of longer life in the city. A series of pictures of the successive members of the house gives added interest to the little book.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held January 6, 1905.

DR. ROBERT T. MORRIS, CHAIRMAN.

Cases of Surgical Disease of the Kidney or Ureter.—Dr. GEORGE EMERSON BREWER exhibited a number of patients who had recently been operated upon for renal or ureteral lesion. One of this series had been a case of peculiar interest. The *x*-ray, ureteral catheterization, and all other signs, pointed conclusively to the presence of an impacted stone in the ureter. On section, however, no calculus could be found, even though retrogade catheterization of the ureter was performed. Dr. Brewer believed that this patient had passed the stone into the bladder during the time that elapsed between the examination and the operation. This view, he said, was endorsed by the fact that since operation there had been no symptoms. Another case of peculiar interest was one in which posterior section was done, the kidney and ureter being exposed in the expectation of finding a calculus. After having demonstrated that there was no stone in the urinary passages, Dr. Brewer observed a hard resisting nodule, which was found to overlie the ureter. On careful dissection, this was observed to be composed of two integral calcareous masses. On separating these, one was found to lie just without the abdominal cavity, while the other, within, was definitely shown to be the calcified tip of an epiploic appendix. The speaker considered this to be of the very greatest importance, because it demonstrated clearly at least one source of the annoying and little-understood bodies which cast *x*-ray shadows and which were most difficult to differentiate from true renal calculi. Another patient was exhibited to show how extensive traumatism of the kidney could be disassociated from shock. The patient had been struck and knocked down by a trolley car. He was placed in Roosevelt Hospital and kept under observation, although he presented no signs of injury, except a very slight fulness in the flank. Suddenly, and without warning, his condition became very grave, so much so that laparotomy was immediately done. The abdominal cavity was found to be normal, but there was hemorrhage from the retroperitoneal space. The abdominal wound was quickly closed; an infusion of 3,000 c.c. of saline solution was given, and the usual renal incision made. The kidney was so badly injured that one large fragment of it floated out with the blood through the wound, and the examining hand readily detected the remainder of the organ torn in two irregular pieces. The patient's condition was by this time so grave that clamps were simply applied to the pedicle and he was hurried to bed. Dr. Brewer presented this case as a striking example of extensive renal laceration without any early symptoms.

In speaking of the value of the *x*-ray in determining the presence of ureteral stone, Dr. Brewer said that the rule followed by Dr. Cole at the Roosevelt Hospital had uniformly proved satisfactory. A positive diagnosis was not to be made unless the outlines of the psoas and of the transverse processes were clearly discernible and unless the edge of the supposed stone shadow was clearly defined.

Mr. E. W. CALDWELL said that he was very glad to have Dr. Brewer's explanation of these peculiar and annoying spots, which not infrequently closely resembled the shadows cast by renal and ureteral calculi. He cited a case which had been subjected to *x*-ray examination in Rochester, with a positive result. The speaker repeated the examination and obtained an exact duplicate. There were three definite shadows approximately in the line of the ureter. Subsequent operation proved that there was no urinary calculus formation whatsoever. True renal calculus shadows should be differentiated by their shape, density, and position. The pseudo-shadows occurred in the experience of the speaker most commonly near the spine of the ischium. He had for this reason believed that they might be cast by a sesamoid bone or bones, occurring in the tendon of one of the obturator muscles. An effort to prove this by changing the position of the thigh, the pelvis having been held *in situ*, had failed.

A Report of Eighty-four Operations on the Kidney and Ureter.—Dr. GEORGE EMERSON BREWER read this paper (see page 241).

Dr. F. TILDEN BROWN spoke of the treatment and diagnosis of ureteral calculus. He endorsed a method which had proved very satisfactory in his hands for the differentiation of false from true calculus shadows. The technique consisted in passing a styleted catheter into the ureter and radiographing this *in situ*. He stated that the false shadows were most frequently seen near the spine of the ischium. The definite shadow of the stylet determined positively the course of the ureter and showed all shadows extraneous to this to be spurious. The second point made by the speaker was in connection with the case shown by Dr. Brewer, in which the calculus had been passed just prior to operation. Acting on a suggestion received from a similar experience in his own practice, Dr. Brown had in a number of cases succeeded in dilating the uterer with sounds and by subsequently injecting boric acid solution above the stone so as to increase the *vis a tergo*, had effected the removal of the stone without operation.

Dr. WILLY MEYER spoke of the necessity of tying the distal end of the severed ureter after nephrectomy for tuberculous kidney. On account of the impotence of the ureterovesical valve, the other kidney might undergo secondary infection. The speaker emphasized the diagnostic value of the appearance of this valve as seen through the cystoscope. He considered nephrectomy to be an operation of distinct value in multiple abscess formation in a single kidney.

Dr. M. S. KAKELS said that the value of the color scheme of the urine—chromocystoscopy—had recently been shown to be greater than generally supposed. Methylene blue, if injected anywhere in the body, would produce, under normal conditions, a urine definitely but unsatisfactorily colored. Indigo carmine, however, if injected into the glutei, would appear in the urine in about fifteen minutes. It was, however, hard to obtain in pure form and very difficult to sterilize. The chromocystoscopic results from this injection were, however, very beautiful, the urine showing a bright distinct color which could not possibly fail to be recognized.

Dr. ROBERT T. MORRIS said that he was able to add to the bodies which might cast a shadow readily to be mistaken for ureteral stones, concretions in the appendix. In a case recently operated on he had found a phosphatic concretion within the appendix bound fast upon the ureter. Such a condition as this would obviously not be revealed by a stylet in the duct. Clinically, he wished to record that if a calculus lay in the ureter near the bladder the tenderness of the lumbar ganglion on that side was marked. If, however, it lay higher up, the tenderness was about the semilunar ganglion. He cordially endorsed Dr. Brown's idea of dilating the ureter and washing out the stone.

Dr. Brewer, in closing the discussion, said that in the treatment of multiple septic infarcts of the kidney, he was firmly convinced that nephrectomy in severe cases was the only operation which could save the patient.

Ureteral Meatoscopy, Preliminary Report of Clinical Studies.—Dr. WALTER C. KLOTZ read this paper. He said that, although the importance of ureteral catheterization had been generally recognized for some time, it must be confessed that the method possessed some distinct disadvantages and very certain limitations. Occasionally the findings in a given case of supposed renal disease were disappointing. This could not be expected to be otherwise, since in a number of renal diseases the urine was negative. One of the most lasting benefits that had been conferred by the extensive researches in ureteral catheterization lay, the speaker said, in the fact that it had incidentally

drawn attention to the conditions of the ureteral orifices. Not only would a study of these openings enable one to determine the fact of the escape of pus or blood, but it had also been shown that in cases of renal disease, irrespective of the character of the secretion as seen at the time of inspection, the ureteral orifice on the same side as the disease presented an appearance differing very distinctly from that of the normal. Enough work had not yet been done to classify the interesting phenomena observed, nor to determine their clinical significance, except in a gross way. The observations made in twenty cases were confirmatory of the view that much important clinical information was to be gained from a careful study of these orifices. In four out of five cases of nephrolithiasis, changes were noted in the ureteral orifice on the diseased side. In one case of supposed nephrolithiasis in which no change was noted, the calculus was found, as reported by Dr. Brewer, outside the ureter. The speaker said that although the series was obviously too small to be accepted as a basis for definite conclusions, the results went far to show that ureteral meatoscopy might in the future to a very considerable extent replace uteral catheterization. Before, however, it could be placed upon an absolutely safe clinical basis, it would be necessary to determine first what constituted a normal and what an abnormal orifice, and, if possible, what were the causes of the changes which took place at the stoma and lastly whether the absence of change in the orifice was of any value in making a negative diagnosis.

Cryoscopy in Renal Disease.—Dr. W. W. Miller read this paper. He said that cryoscopy might be considered the most reliable method for determining the functional activity of the kidneys, when used in connection with chemical and microscopical blood and urine analyses. The principles involved in cryoscopy were described as follows: Blood serum consisted of a watery solution of certain substances. In circulating through the kidneys it had been shown experimentally that water and salt, notably the chlorides, were excreted from the glomeruli and that in the tubules this fluid came in contact with the blood through the medium of the excretory epithelium. Biological and osmotic forces played an equal part, in all probability, although this had not been definitely proven. Certain it was, however, that at this point an exchange of water and salt for the urea was made. It should be remembered that cryoscopy depended upon molecular concentration rather than upon specific gravity, the freezing point of fluids depending on the osmotic density. It had been found by Kümmel and others that the freezing point of the blood was a much more constant quantity than that of the urine. The variations in disease should, therefore, be looked for in the blood. The best instrument was some modification of the Bechmann apparatus. It consisted simply of a vessel to contain the 20 to 30 c.c. of fluid to be examined. This should be surrounded by another, which was filled with a freezing mixture. The temperature of this should not exceed —4° C. An air space should surround the fluid, so as to permit of its gradual cooling. The thermometer should register in hundredths of one degree. As the fluid cooled the mercury was carefully watched. It fell to a point some distance below the actual freezing point, and at the moment of freezing suddenly rose. This was due to latent heat. The maximum point to which it ascended registered the true freezing point. A point in the technique was that the bulb of the thermometer should be entirely covered by the liquid, but should not touch the bottom of the vessel. Kümmel, in a study of 500 cases, had shown that the freezing point of the blood varied normally from 0.54 to 0.58. In a group of patients suffering from chronic nephritis, the variation was from 0.58 to 0.80.

Dr. George E. Brewer said he was convinced that in a certain class of questionable cases cryoscopy was of greater value than any other known test.

Election of Officers.—For *Chairman*, Dr. S. Lloyd; for *Secretary*, Dr. W. S. Bicham.

NEW YORK ACADEMY OF MEDICINE.

Section on Pediatrics.

Stated Meeting, Held January 12, 1905.

Dr. L. E. LaFétra, Chairman.

A Case of Empyema Apparently Cured without Operation.—Dr. L. E. La Fétra presented a boy whom he had first seen at the Vanderbilt Clinic in November last. The family history, as regards tuberculosis, was negative. The patient had been perfectly well until September last, when he was four and a half years old; he then had an acute illness which was supposed to be typhoid pneumonia. From the description given it was evident that the child suffered from some type of pneumonia. The child had a high temperature and cough, especially during the first part of his illness. After that acute illness he was apparently well for two weeks, regaining weight and strength rapidly. During the middle of October he again began to cough. There was no expectoration. The cough was more marked in the morning. He lost appetite, was weak, and had some pain in the abdomen on exertion. Before coming to the clinic he had been having fever in the afternoon and night sweats. The physical examination, at the time of his first being seen, showed flatness from the base of the right chest up to about the angle of the scapula, and Skodaic resonance above the fluid. The heart was displaced to the left about one inch. A needle inserted in the space between the scapulæ withdrew one-half a syringeful of pus. It was regretted that this pus was not carefully examined; it was assumed that when the child came to operation later on, the pus would be carefully examined. It was quite difficult to withdraw the pus because of its thickness. On November 5 the child was sent to Roosevelt Hospital, to the surgical side, with the idea that an operation for empyema should be performed. The next day, *i. e.* three days having first been seen, the child was taken to the operating room, and four or five punctures made by the House Surgeon, but the needle failed to find any pus. This search for pus was again made the next day but none was found. No operation could be performed if no pus was found with the needle. The boy returned to the Vanderbilt Clinic on the 10th, and was examined by other men there, and they too felt sure that there must be pus present. A large needle was introduced at the angle of the scapula, and persistent and determined efforts were made, but no pus could be found. By November 30 the child had greatly improved, the dullness had markedly diminished, the heart was in its normal position, the voice sounds had increased so as to be quite perceptible. On December 6 the râles were fewer, the breathing could be feebly heard over the area of dullness, the voice sounds were still exaggerated but had somewhat the bronchial character. December 20 showed the boy to be very much improved, with only a slight dullness, the breathing sounds being nearly normal, and the temperature by mouth being about 100° F. The child had never coughed up mucus or mucopus and, therefore, there could not have been much discharge from the bronchi.

Dr. Henry Koplik said that in Dr. La Fétra's case there were two possibilities; the greater portion of the pus might have been removed by aspiration, and then the boy was able to dispose of any pus that remained by his own natural powers of resistance, or, again, the effusion left might have become inspissated, the bacteria less virulent, and simply a thickened pleura might have been felt. If this was a true case of empyema he doubted whether it could have been cured by simple aspiration. In many hospital cases where pus had been found before admission, it could not be found afterwards; perhaps two or three months later it would be found and operation performed. He said that in cases where other physicians claimed to have found pus and he was unable to find it, he kept the patient under

observation, percussing the chest once a week or oftener, and if flatness was observed at any time, he felt warranted in making further exploration.

Dr. Henry Dwight Chapin asked Dr. Koplik if he had found protracted high temperatures in cases of this kind.

Dr. Koplik had observed that the temperature might remain low for weeks and then suddenly rise two or three degrees.

Dr. Chapin related an instance in which a child of two years had had pneumonia, which had apparently resolved, the temperature remaining normal for about ten days. At that time a member of the house staff inserted a needle and found pus. Dr. Chapin believed that such cases usually ran hectic temperatures.

Dr. Joseph E. Winters told of a case that he had diagnosed as one of empyema, and in which, under an anesthetic, puncture was performed six times with negative results. The patient was kept under observation for many months when it was discovered that the pus had burrowed through the right crus of the diaphragm, appearing well down in the lumbar region, where it was opened as a superficial abscess; the patient made a good recovery. He also cited another case which had been diagnosed as empyema, but upon incision no pus was found. The patient was in the hospital for some weeks, then went home; but was operated upon later with success. It was his opinion that pus was still present in the case presented by Dr. La Fétra and that the patient should be watched for months before he could be pronounced cured.

Dr. Matthias Nicoll, Jr., took exception to Dr. Koplik's remark in regard to deferring operation if an unresolved pneumonia was present. In many autopsies upon these cases he had found that in at least 50 per cent. there was a sufficient amount of turbid fluid present to embarrass respiration, and this condition would have been relieved by operation. He believed in relieving the mechanical embarrassment even though the child's lung was solid.

Dr. La Fétra in closing the discussion, said that he had designated the child as "apparently" cured, because the auscultatory signs had markedly lessened, the breathing and voice sounds had improved, the temperature had gone down, and the child had gained in weight. He had had a similar case where operation revealed only an edematous pleura. He believed, however, that in every case of empyema it was the duty of the physician to operate, because the chances of recovery were otherwise small.

Standardized Gruels; the Application of the Percentage Principle to Cereal Feeding.—Dr. Henry Dwight Chapin read this paper (see page 246).

Dr. Joseph E. Winters asked Dr. Chapin if he intended to state that these cereals were to be used in young infants, and received an affirmative answer. He said that cereals could take the place of milk only after a certain period of life, and that up to that time they were not only useless but injurious. Babies fed on gruels made of cereals during the summer months became ill and failed. Babies from the age of one month up to the age of six months, suffered from the gravest malnutrition when fed on cereal gruels, and made a rapid recovery when the milk diet was substituted. The work done recently by Dr. Shaw of Albany, showed conclusively that infants could not digest cereals. Dr. Winters acknowledged that there was a use for these cereal gruels, but not before the age of six months, and in summer not before the seventh or eighth month, and if the child had diarrhea not until the age of one year. After that time he believed the cereals should be the almost exclusive diet of the child. In children one year old or over, he thought the gruels should take the place of broths now so extensively used.

Dr. Henry Koplik said that he was unable to understand why there should be such a radical difference of opinion on this question. He always tried to find what the baby needed, and whatever suited the baby suited him. He had fed babies on cereal gruels from birth, and they had thrived beautifully. In atrophic conditions the greatest benefit was to be derived from this kind of feeding. Wheat flour was one of the most important foods we now had. He said that he had fed twins on wheat flour from birth, when they could not digest cow's milk, and that they were now one year old, and thriving. He had had a large experience, and would reiterate the statement that babies would thrive from an early age on gruels when they would not thrive on some modification of milk with water.

Dr. Thomas S. Southworth said that there were two kinds of work which were valuable in unraveling the problems of infant feeding, one the purely scientific inquiry into fundamental principles, and the other the practical application of these principles to every-day work. We had now passed the time when we believed that we could manufacture any counterpart of the breast milk. Dr. Chapin did not recommend cereals alone in the daily feeding of children, but the use of cereals had an immense field in those cases where milk had to be omitted for a time. One could not expect to nourish a child for a considerable period with cereals as the whole food. Cereal gruels were good when a radical change of diet was imperative. He said that this food was *par excellence* the food in the summer diarrheas of children. By the methods used for dextrinizing gruels, sugar was formed, and none would deny that that sugar could not be absorbed by young children. These cereal gruels sometimes caused too much fermentation. He thought the time was ripe for some real and exact knowledge concerning infant feeding.

Dr. J. Finley Bell said that two years ago he did some work on the chemistry of gruels, and had learned several facts not touched upon by the reader of the paper. He divided foods into three classes, the alkaline, the neutral, and the acid, and those that Dr. Chapin had reference to would fall under the last variety, the ash of these foods not being alkaline in reaction but sometimes acid. Gruels, when boiled for some time, would develop purin bodies which were inimical to infant feeding.

Dr. Joseph E. Winters, in defense of the position assumed by him, said that when a baby was fed on milk with cereal gruels added, and that baby thrived, one could not prove that the gruels had anything to do with it. Cereal gruels must be used in combination with milk and not alone; no child under six months should ever be fed on cereal gruels alone, although at a later period in life they would thrive on them.

Dr. Roland G. Freeman believed that babies did better on simple modified milk; but if they could not digest this well, then the cereals could be added with benefit.

Dr. Koplik said he had never heard of feeding babies on cereal gruels without the addition of milk, and he had never thought of such a thing, except in some acute illness when they could be given for short periods of time. In some cases, milk alone would not nourish the infant; then the addition of gruels would.

Dr. Chapin closed the discussion, and referred briefly to what he had already written on the biology of cow's milk, and called attention to the fact that milk had two functions, one the nutritive, and the other the function in developing the alimentary tract. When cow's milk was placed in a baby's stomach it really was a foreign body, and it was not physiological. Substances should be added to it which made it more readily digested, and which added to its nutritive value. He said that no one system of infant feeding would always succeed.

Piscine Pathology.—Among the patients at the hospital for diseased fishes, recently established at Vienna in connection with the new chair of fish pathology and biology at the university, are a carp being treated for an inflammation resembling appendicitis, ten others suffering from smallpox, a porpoise from the Adriatic with inflammation of the lungs, a trout with cataract of both eyes, and another with dropsy.—*St. James Gazette.*

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 23, 1905.

Dr. Henry S. Stearns in the Chair.

A Century's Criminal Alliance Between Quacks and Newspapers.—Mr. Champe S. Andrews, Counsel to the Society, delivered this lecture, and illustrated it with stereopticon views taken from typical quack advertisements of the last one hundred years, contained in his private collection of American newspapers. He said he had recently delivered a lecture before the Society of Medical Jurisprudence entitled "Medical Quacks, Their Methods and Dangers," which was to all intents and purposes a résumé of his work for several years as counsel of the Society; in it he described every class of medical fakir that had ever come under his observation, and in many instances he told of the types of quacks who had been convicted through the efforts of the Society. The newspapers laid great stress on an alleged statement of his to the effect that there were twenty thousand quacks in the City of New York, and this statement was the subject of much editorial comment. As a matter of fact, the most important statement made in that lecture was one to the effect that newspaper publicity was the life of the modern quack. In connection with this statement, he dwelt upon the duty the press owed to the public to refuse certain classes of medical advertisements, chiefly those designed to reach the consumptive poor, the youth suffering from venereal disease, and the young woman in a delicate condition. The newspapers completely ignored any reference to this part of the lecture. On the other hand, in the editorial comments of several New York newspapers, the statement that there were twenty thousand quacks in the City of New York was made the basis of more or less adverse criticism on the work of the Society. He said that the two papers in which almost every kind of medical advertisement was unblushingly exploited, were particularly severe. These criticisms called forth a temperate and dignified statement from the Comitia Minora of the Society, which was sent to the morning papers in New York City, in which attention was called to the fact that medical quackery could never be suppressed in the City of New York until the newspapers closed their columns to medical advertisements. Again, this feature of the subject was ignored by the newspapers, and most of them failed to print the explanation, so far as he had been able to learn.

If publicity was the life of the quack, newspaper notoriety was his undoing, and if the decent newspapers in the City of New York would tell the simple facts regarding the dangers and the degradation caused by some of the advertisements they print, a great public abuse would be done away with, many thousands of dollars would be saved to those least able to part with their hard-earned funds, the health of the young men could be repaired, and the honor of many young women would be saved.

The object of Mr. Andrews' lecture was first to indicate the development of quackery, showing how it had changed its methods as the level of general intelligence had increased. The ancient prototype of nearly every known variety of the modern medical fakir was shown. When the daily newspaper was founded, that day the villainies of the criminal quack became possible. Second, he wished to show just how the newspaper advertisement acted as a net in which innocent young men and boys were caught and then exploited by men, who for gain prostituted the health, the means, and honor of their victims. If this could be established in a satisfactory way, he said that it must necessarily follow that the press should be condemned for aiding and abetting in these felonious practices. Mr. Andrews was the owner of what was perhaps the best collection of American newspapers in existence outside of the great libraries. It included over 60,000 newspapers, and covered every day and every year since Washington's administration to the close of the Spanish war. At great length he had studied the history of quack advertisements and traced their development through the nineteenth century and since in American newspapers. In order that he might not be accused of exaggeration he had had over fifty typical advertisements photographed, and he presented them by means of the stereopticon.

Hon. Edward E. Ommen, City Magistrate, was very frank in stating that he had strong views regarding newspaper advertising, and he said he was perfectly satisfied that if the newspapers would cease medical advertising the counsel for the Society would be out of a job. Nobody could estimate the amount of injury these advertisements did the young men and women of this great city. He thought the Society should, through some means, possibly by mass meeting, try to arouse public sentiment, and anything the Society did in this respect would redound to its credit, and would be a great and meritorious work. If public sentiment could be so aroused the newspapers would have to give way, because nothing could stand against public clamor. But the Society should go about it in a systematic manner. He said he, as City Migistrate, would be glad to assist in any way he could.

Mr. Theodore Sutro said that it was not the newspaper advertisements only of the quack that did harm in any community, but the circulars and pamphlets which were so freely distributed, and this was more ancient than newspaper advertising. The unholy alliance between quacks and newspapers, he understood the lecturer to state, had only existed 100 years, but he read a few advertisements that were published 250 years ago, all in London papers. He said that this hankering after quack medicines was in reality the result of the inborn hankering for the mysterious, the unknown, and the unfathomable. This hankering was at the basis of all superstition. The newspapers were culpable because it was the weak, the ignorant, and superstitious who were entrapped by their advertising. Mr. Sutro asked what could be done to remedy this evil. Mass meetings and public protests had been suggested, but he did not believe they would succeed. Could a censorship be established? Not in this country because it was against the law. Could they be reached by law or legislation? No. Might the newspapers be effective in attempting to remedy this? Yes, if they would, but it should be remembered they were money makers, and wished to pay large dividends to the stockholders, that corporations had no souls, least of all newspaper corporations. The only remedy that would reach the evil and be effective would be to educate the people and cultivate the public taste. Men of family should exclude such papers from their homes, and thus counterbalance the profits made by newspaper quack advertising.

Mr. Robert C. Taylor, Assistant District Attorney, New York County, said he did not then see any remedy to break up the unholy alliance between quacks and newspapers, for the constitution forbade anything which interfered with the freedom of the press, and no legal steps could be taken against newspapers for inserting these advertisements. He said that the work of Mr. Andrews had filled the District Attorney's office with admiration. He tendered the Society every facility possible from the District Attorney's office in their efforts to suppress this unholy alliance between quacks and newspapers, and in the conviction of quacks.

Dr. Frank Van Fleet said that we could not expect to reach the millennium in this matter, but the conditions could be improved very much, and there were many simple ways by which it could be brought about, such as the enforcement of the medical laws, and by the medical profession being alive to its obligations to the community and undertaking its education in these matters. In order that work might be accomplished, the best efforts of the medical men of the State of New York were asked for in bringing about medical union. When this was accomplished he believed the medical profession would be in a position to do something, but not before.

Dr. Prince A. Morrow said that one could not make

a correct mathematical count of the number of cases of private diseases treated by quacks in this country, but in Germany it was known that from 25 per cent. to 50 per cent. of all cases of this character were treated by quacks. In the New York Hospital, 30 per cent. of the men coming for treatment had been treated by these quacks. He had no remedy to suggest for the relief of this great evil. The vast majority of these victims he believed to be young men who were brought up in ignorance of sexual physiology and hygiene, and he did not believe that we could ever correct these conditions until these young men were better educated regarding sexual matters. The greatest offenders in medical quack advertising were the Boston newspapers; recently one paper there had nineteen of these advertisements occupying two columns.

Dr. S. A. Knopf spoke of some of the schemes of the consumption quacks, one of the most notorious of whom Mr. Andrews had put out of business. Among the many victims of these advertising quacks were to be found a large number of the tuberculous poor.

Dr. Sidney D. Jacobson thought that we could learn much from other countries in the way of putting down quackery, and he briefly referred to the methods employed in England and in Germany.

Dr. Wendell C. Phillips said that when public sentiment was aroused, it then, as a rule, accomplished what it set out to accomplish, and meetings of this kind were steps in the right direction. He referred to a certain religious journal that guaranteed to insure its readers against loss of money as the result of patronizing those who advertised in its pages; as a result of this the financial condition of this journal was much improved, for it made more money. If the great journals of this country could be shown that legitimate advertising paid, much could be accomplished in the suppression of quackery, especially when combined with an aroused public sentiment.

Mr. Andrews said that the Boston *Herald* would never receive an advertisement from a medical quack, and, as a result of this determination not to publish more of them, it had received letters of commendation from all over the United States. If the medical profession in this State was united, many bills could be passed at Albany which now were impossible. In all his work as counsel for the Society he had been most courteously treated by the District Attorney and those in his office.

Amalgamation of the Two State Medical Bodies.—A resolution was unanimously passed That the Medical Society of the County of New York expresses approval of the action of the Medical Society of the State of New York in all matters pertaining to the amalgamation of the two State bodies; That the Medical Society of the County of New York also expresses grateful appreciation of the arduous labors of the special committee appointed by the State Society to bring about the union; That the Medical Society of the County of New York instruct its delegation to present to the State Society at its annual meeting, to be held at Albany, January 31, February 1 and 2, 1905: (1) Its regret that legal difficulties prevented immediate amalgamation; (2) a recommendation that the State Society make such changes in its present Constitution and By-Laws at the coming meeting as will remove any possible legal difficulties which might arise to prevent amalgamation; (3) an earnest recommendation that the present committee which represents the State Society should be continued without change in its membership.

NEW YORK PSYCHIATRICAL SOCIETY.

Stated Meeting, Held January 14, 1905.

Dr. Allan McLane Hamilton in the Chair.

The Role of Habit Disorganizations in the Essential Deteriorations (Dementia Præcox) and the Relation of the Deterioration Process to the Hysterical, Neurasthenic, and Psychiasthenic Constitutions.—Dr. Adolf Meyer read this paper. In order to move from the standpoint of statistical etiology to that of the actual tracing of pathological factors in the individual case, he said, the study of the constitutional makeup and of the development of such constitution was an imminent task. As a prominent point habit disorganizations presented themselves; they were usually traced to peculiarity of hereditary endowment, but certainly also depended on the influence of the environment, and it was remarkable how just in the disorders which might figure as essential deterioration processes—that is, deterioration not due to alcohol or any of the other exogenous damages to the brain, disharmonies of habits could be shown to develop sometimes from small beginnings, taking in more and more of the functions which ought to depend on a sound automatic regulation, without our being obliged to assume that these developments were quite irremediable and to be left to fate altogether. Roux's mechanics of development furnished an excellent illustration of the interference of untimely development of special functions in the normal regulations of other functions. The gradual development and spreading of disharmonies were shown in a few cases with precocious sexual development. And stress was put on the importance of the recognition of the whole disharmony for a farsighted treatment of the constipation, amenorrhea, and other matters which usually received medical attention. It was of the utmost importance to correct these disorders, but without due attention to the necessity of habit-training, such patching up was usually of little influence. In connection with some of the habit disharmonies found in the deterioration types, the question of the relationship of the deterioration type to the other constitutional types, as published by the writer in the *American Journal of Psychology*, Vol. 14, pp. 90-103, was more fully discussed.

Dr. Graeme M. Hammond said that it seemed to him, particularly when viewed from an alienist's standpoint, that nearly all deviations from the normal mental state, in children particularly, were classified as dementia præcox. Many cases of true paranoia were frequently classified among the cases of dementia præcox. He was sure that children who were peculiar, who did not associate with other children, who were masturbators and irreligious in childhood, never developed into anything at all, and many of them became normal citizens, never becoming paranoiacs or victims of dementia præcox. In just such a way one might see deviations from the normal physical condition or deviations from the normal mental types.

With regard to the matter of heredity, he believed that was even more important than the history of insanity in parents as a cause of dementia præcox. Many cases of dementia præcox, paranoiacs, etc., were seen where insanity could not be traced among their ancestors. Another cause more frequently encountered was syphilis; another was alcoholism; sometimes both existed as causal factors, in one or in both parents. He believed that a syphilitic parent was more apt to beget true dementia præcox or paranoiac cases than, in all probability, true insanity.

Dr. Hammond made his diagnosis of dementia præcox from the symptoms presented, and not from any antecedent history. Neurasthenic and hysterical individuals were particularly prone to dementia præcox; such cases frequently begin as neurasthenia or with hysterical symptoms.

Dr. L. Pierce Clark said that his opinion in regard to the subject of the evening was somewhat different from that expressed by Dr. Meyer, although he agreed with him in the main. He considered the hereditary element (almost 80 per cent.) as much a factor in the production of adolescent insanity as syphilis in tabes or general paresis. It seemed to him that in time the forms of insanity embraced in the term dementia præcox might be synonymous with hereditary mental degeneration of the adolescent period. We must scrutinize the family history more closely than simply to determine the presence or absence of insanity.

There were many and varied neuropathic factors in the parent which were difficult to detect, but were none the less determinent for degeneration in the offspring. Alcohol, syphilis, chronic rheumatism were no more important in this regard than a vicious type of habits of life and conduct. He believed that in a great number of cases one might ultimately find a more or less definite correlation existing between the amount of hereditary handicap and the degree and character of mental deterioration in a given case. It was known that in a few cases very marked mental deterioration was not in evidence. Some authors had gone so far as to say either dementia præcox did not invariably end in dementia, or did not embrace all the insanities of the adolescent period. He believed that at least some degree of dementia was as much the *sine qua non* of dementia præcox as marked mental deterioration was in general paresis. In regard to the pathology of dementia præcox, he said while an autointoxication might be an inciting agent, undoubtedly the heredity predisposition, possibly embraced in a neurofibrillary anomaly in cortical development, was the condition most signally at fault. He urged the necessity of more thorough investigations of the intercommissural and association tracts, as well as the disorganization of the fibrillary intercellular network which, according to the most elaborate investigations of Bethe, Apathy, and Held in cortical researches would be found to play such an important part in normal and morbid cerebral functions. Possibly the mystery of the degenerative defects of dementia præcox, where the gross appearance of the brain seemed so normal, might at last be cleared in these neurofibral studies. He believed the apparent complexity, vagueness, and anomaly of mental symptoms in some cases of dementia præcox must be explained upon involutional as well as evolutional lines. Nerve defects occurring in the evolutional periods of life were always more widely variant and bizarre than after the organism becomes more fixed. To clarify our knowledge of the mental disease of adolescence we need larger data, from many widely different localities; cases drawn from different strata of society, both in and outside of asylums. Only such collaborative studies, undertaken upon an extensive scale, could hope to fully harmonize our present very discordant views upon the subject.

Regarding the treatment, he said it was but logical to hold that the prophylaxis and conservation of incipient cases rested upon the possibility of the earliest diagnosis. By taking advantage of medico-pedagogics, disciplining improper habits, as Dr. Meyer suggested, one might stay the progress of deterioration, as had long been the rule in other degenerative disorders of the nervous system, such as in epilepsy and feeble-mindedness, for example. Sufficient data were even now at hand to show that many cases of dementia præcox might be and were saved from grave dementia by proper systems of hospital and sanatorium training, treatment, and care. One certainly could not hope to cure the dementia which had already taken place, but one might bring about an arrest of degeneration which would be more or less permanent. The earlier the diagnosis and the earlier the treatment, the more hope we might extend in dementia præcox.

Dr. Emmet Cooper Dent said that he most heartily concurred in Dr. Meyer's method of history taking; in fact, he had been following out this line of work in the Manhattan State Hospital, on Ward's Island. He said that this method of systematic history taking would go far toward showing that theory and facts were not going hand in hand, as some text books would have us believe. During the past year there were admitted to the hospital two hundred and ninety, or 31.7 per cent. of the total number of admissions, grouped under this classification. Ninety-nine were placed under the hebephrenic type. One hundred and thirty-four were of the paranoid type of dementia præcox. Fifty-seven were placed under the catatonic type. The average age in the hebephrenic type was about sixteen, eight apparently recovered. The average age of the paranoid type was about twenty-five years, and two were discharged apparently recovered. The average age of the catatonic type was twenty years. Six were discharged apparently recovered. In many instances a careful investigation failed to bring out heredity, but this was much more frequently established in the hebephrenic than in the other two. The questions relating to dementia præcox and the diagnosis of it were of considerable importance. He agreed with Dr. Clarke that dementia præcox was eminently a disease of deterioration, as was dementia paralytica, and he did not believe that a true case of dementia præcox existed without deterioration. Much care and attention were being devoted to history taking and study of all psychoses, and it was hoped by this system to be able to deal more frankly with facts, which, after all, were what was needed, and not opinions. The name dementia præcox he believed to be a very unfortunate one, and served as a cause for dispute, contention, and misunderstanding for alienists.

Dr. Allan McLane Hamilton said that, if he understood Dr. Meyer's claims correctly, the latter did not use the term dementia præcox in an arbitrary manner, but that he referred to those borderland and imperfectly understood psychoses which, though they bore a relation to certain conspicuous and conventional types of insanity, yet their origin and development was usually lost sight of. The clearly ascertained history of heredity, which, of course, was found in most well-marked cases of dementia præcox, might undoubtedly be absent in these essential forms of mental disorganization. Dr. Hamilton said such states might be the outgrowth not only of a subtle, transmitted weakness, but also of some defect in development, education, environment, or of the example alone, of a psychopathic parent; or, again, there might be remote syphilis, or some of those influences which prevented the subject from properly adjusting himself to society at large. Dr. Hamilton called attention to the general ignorance of parents, teachers, and the community especially, when the question of responsibility arose in such cases. Much vice imperfectly understood, and moral disorder of a like degree, were familiar enough to criminologists and phychiatrists. The study of such cases, with relation to emotional epidemics and criminal example, would reveal the genesis of unclassified insanities, and he had been impressed with the parallelism between certain pubescent insanities and the process of "getting religion," where the morbid mental operations of the patient were closely allied. He believed that if the public could be made to recognize the morbid changes of the mind, as the result of the stress of a struggle with the world, much could be done in the way of prevention. The reader of the paper had called for greater care in the study of cases, and Dr. Hamilton had, himself, in other days, been impressed with the fact that in every asylum, the history books practically showed that the patients entered these places with a blank behind them, so far as a knowledge of the evolution of their condition was concerned. If such a thing were possible, every large asylum should have an investigating member of its staff, whose sole duty it should be to determine, outside, not only the past history of the admitted patient, but also his family relations and environment as well.

Dr. Adolf Meyer, closing the discussion, wished to correct the impression that he used the term dementia præcox in any such way as Dr. Hammond thought he had used it. He said he explicitly started his paper with the statement that he was considering a certain number of cases which were finished and recognized cases of obvious deterioration, simply in order to take a definite starting point for getting at a special principle of pathology and morbid development, irrespective of whether it would be limited to dementia præcox or something else, and in the hope that he might get more specific definition of that which would lead to deterioration types or neurasthenic or other constitutional make-up, such as might be present without having anything to do with dementia præcox. The

suggestion of habit disorganization aimed to recognize facts which were tangible, rather than deal with "mights," "probables," "usually," with mere possibility of syphilis, alcoholism or what not; they wished to emphasize those things which could be demonstrated having an actual bearing on the development of the actual patient. They were after something definite and tangible, and not the general doctrines of fatalism. Dr. Meyer said he was far from minimizing the importance of heredity as a statistical fact; but his discussion insisted upon certain important things in the life of the patient that were to be considered on the same ground as the principle of regulations in Roux's work; he looked for the stunting influences in distinct traits of development through the untimely, excessive, or deficient function of one set of activities or another. He said it was the alienist's task to discriminate between hereditary disorders which could be influenced, in contradistinction to those which must be accepted as irreparable. Some of Dr. Clarke's remarks about heredity corroborated his general view. Any family with irregular habits would form an ideal ground for a child to develop disharmonies of habit. Dr. Meyer said that the real issue of his paper was not so much the discussion of dementia præcox as to draw attention to some simple working principle of the development of constitutional types without theoretical encumbrances.

Chicago Medical Society.

At a meeting held January 25, 1905, Dr. Wm. Allen Pusey read a paper entitled "The Therapeutic Use of the X-Ray: Three Years Later." The author reviewed his early work with the *x*-ray as a therapeutic measure, and pointed out the therapeutic limitations and possibilities of the agent. His results in the treatment of hypertrichosis with the *x*-ray were satisfactory in only 50 per cent. of the cases, and even in these it was necessary for the patients to undergo prolonged treatment. In sycosis and tinea sycosis the *x*-ray was of great value as a therapeutic agent. His results had been very satisfactory in the treatment of acne with it. In rosacea the results had been quite as satisfactory as in acne. The *x*-ray was particularly valuable in treating chronic inflammatory dermatoses, such as eczemas of the hands. Excellent results were obtained in chronic indurated eczema of other parts. The ray was markedly beneficial in psoriasis and lichen planus, although it did not offer striking advantages over other methods of treatment. He had not seen the benefit from the *x*-ray reported by other observers in cases of pruritus ani and vulvæ. His experience was favorable in treating pigmented and vascular nevi with the ray; also cases of keloid and scars. He had treated successfully eight or ten typical keloids, most of them being on the chests of women. His experience in treating lupus vulgaris with the *x*-ray corroborated the value of it as mentioned by other observers. He mentioned its beneficial effects in the treatment of cases of cervical adenitis, tuberculosis of joints, blastomycosis, epithelioma of the lower lip, cancer of the neck, and in pseudoleukemia and leukemia. Dr. Pusey reported his failures as well as his successes. His experience had taught him that the *x*-ray was of little or no value in the treatment of goitre.

Dr. Joseph A. Capps and Dr. Joseph F. Smith contributed a joint paper on "The Treatment of Lymphatic Leukemia with the *X*-ray." In summing up, the authors stated that splenomyelogenous cases of leukemia should receive *x*-ray treatment, because they are greatly benefited. They responded more slowly than did cases of chronic lymphatic leukemia. There was so much benefit that the patients themselves felt they were cured, but in the light of Senn's patient, and of others reported as symptomatically cured, but some of whom had since died, they stated that physicians must not be too sanguine in regard to pronouncing cures. Undoubtedly, the *x*-ray exerted a wonderful modifying effect, and was a very good method of treatment for the alleviation of symptoms in lymphatic leukemia and splenomyelogenous leukemia, but probably it did not effect an absolute cure.

Dr. H. J. Burwash read a paper on "Administration of Oxygen Gas." Reference was made to the experimental work of Kellogg on guinea pigs, which showed that gas per rectum was readily absorbed, and that dark venous blood was noticed to be immediately changed into bright arterial blood by its application. Kellogg, therefore, recommended the method for the treatment of diseases of the liver and digestive organs. Dr. Burwash had made a new application of it by using it in the treatment of acute respiratory diseases, particularly pneumonia. This method was first used by him in August, 1891, in a severe typhoid fever case, after failing to resuscitate the patient by the usual method of inhalation. The patient was a young girl, sixteen years of age, who, after a persistent high temperature, became perfectly toxic, delirious, and cyanotic. The gas by inhalation did not appear to revive her from the stupor, and then it occurred to him to administer the gas per rectum. He gave her one gallon; after two minutes' duration the respirations became more exhilarated, and the deep cyanosis turned to a beautiful pink condition. The patient recovered after a very protracted illness. Since that time he had continued to use oxygen per enema in all of his critical cases, especially pneumonia. He mentioned two recent cases of pneumonia that he had treated successfully with oxygen gas. Why does oxygen gas administered by the intestinal canal oxygenate the blood and tissues so much more efficiently than when given by inhalation? It was apparent to the author that the introduction of a large quantity of oxygen gas into the intestinal canal not only neutralized and deodorized the noxious gases that were frequently present there, but also by this direct method introduced oxygen through the portal system to the liver, whose cells were not only stimulated to greater activity, but were nourished as well. Besides, the already overcharged lungs were assisted in their function of aeration of the blood by this condition of reenforcement.

Intermittent Claudication and Analogous Phenomena (Angina Pectoris, Etc.).—Arthur J. Patek says that intermittent claudication is not a disease *sui generis*, but merely a peculiar clinical manifestation of arteriosclerosis involving the vessels of the lower extremities. He thinks that the study of the cases of intermittent claudication thus far recorded justify the following conclusions: Intermittent claudication is far more frequently a symptom-complex than is generally recognized. It is doubtless often and freely confounded with sciatica, neuralgia, and rheumatism. Careful and detailed inquiry into the symptoms, which usually come on while walking, and are absent when at rest, together with their intermittency, should lead to a suspicion of the diagnosis; this will be made absolute by finding that pulsation is absent in one or more distal arteries (dorsalis pedis and tibialis posticus) of one or both legs. The pain is of vascular origin and due to an arteritis plus—in many cases—angiospasm of the affected vessel. The various internal viscera may suffer from such an angiospasm when their vessels are sclerosed, the most prominent prototype being the heart in the common condition, angina pectoris. Total occlusion of the vessels, as occasionally found in intermittent claudication, may lead to gangrene of an extremity. Early recognition is essential, in order, by appropriate treatment, to prevent this dire and frequent complication. Bodily rest, with warmth and moisture, is a most important element of treatment. The use of alcohol and tobacco must be interdicted, and all excesses and abuses avoided. Hydrotherapy, massage, and electricity appear to be serviceable in some cases. The iodides, vasodilators, and heart tonics are indicated. In the main, however, reliance must be placed upon a therapeusis of general character, not medicinal. When walking is to be resumed, the utmost caution must be observed to avoid undue fatigue.—*The Wisconsin Medical Journal.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 11, 1905:

	Cases	Deaths.
Measles	201	3
Diphtheria and Croup	275	42
Scarlet Fever	246	14
Smallpox	3	1
Chickenpox	101	
Tuberculosis	368	181
Typhoid Fever	28	4
Cerebrospinal Meningitis		29
Typhus Fever		
Yellow Fever		
Cholera		
Totals	1,222	274

Recurrent Vomiting.—B. K. Rachford believes that recurrent vomiting is a symptom group closely related to migraine. It is autotoxic in origin and characterized by recurrent attacks of nausea, persistent vomiting, and great prostration. The great majority of cases occur during infancy and childhood. Sex has little influence. It is somewhat more common in winter than in summer. Heredity is the most important predisposing factor. A family history of migraine or gout is present in nearly every case. A general neurotic inheritance is common. Nearly all of these patients are constipated, and this condition is doubtless an important etiological factor. Mental overwork and excitement, combined with indoor life, are important predisposing factors. Nearly all writers agree that recurrent vomiting is an autointoxication. The writer believes that both auto and intestinal toxins may play a rôle in producing this symptom group. A functional incompetency of the liver is a very important factor. Fatigue, fright, anger, and disappointment are common exciting causes. Overeating is a very potent factor. Warning symptoms are flushings of the cheek, coryza, general restlessness, nervous irritability, sleeplessness, sallowness of complexion, dark rings under the eyes, general malaise, constipation, and loss of appetite. Vomiting follows the prodromes in from six to forty-eight hours. After an attack the stomach, as a rule, resumes its functions. Thirst is a striking symptom. Emaciation is extreme in long-continued cases. Fever is present in nearly every case under ten years of age. The pulse is irregular. Respiration may be sighing, or rapid and panting. Narcotism, the writer has not found uncommon. Gastric pain is not present in these attacks in children. Nervousness is very marked. The urine is very concentrated and strongly acid in reaction. The prognosis in relation to recovery is good. Little is known concerning the pathology of the disease. Calomel and bicarbonate of soda are indicated in the prodromal stage. When food and water are not retained by the stomach, rectal enemata of normal salt solution or bicarbonate of soda solution are indicated. Outdoor life, with moderate exercise, should be advised. The diet should be carefully restricted. Milk, cocoa, vegetable soups, cereals, well-cooked vegetables, cooked fruits, eggs, fish, chicken, mutton, and, ocasionally, beef, may be given. The sources of reflex irritation should be sought for and removed, if possible. Wintergreen salicylate of soda, and the benzoate of soda are the most valuable medicinal remedies. Constipation must be most carefully looked after. Solutions of sulphate and phosphate of soda are usually effective. Abdominal massage is sometimes helpful. General massage is a very valuable remedy in patients of feeble constitution.—*Archives of Pediatrics.*

A Modification of Giernsa's Strain.—Giernsa has devised a modification of his methylene azur-eosin stain, by which only a single solution is employed and the technique is much simplified, while at the same time better results are obtained. The formula for the stain is as follows: Three gm. of azur II-eosin (azur-eosin and methylene blue-cosin) and eight-tenths gm. of azur II (equal parts of methylene azur hydrochlorate and of methylene blue hydrochlorate) are exsiccated, finely pulverized and sifted, and then dissolved in 250 gm. of chemically pure glycerin at 60° C. When solution is complete, 250 gm. of methyl alcohol, at a temperature of 60° C., are added, well shaken, allowed to stand for twenty-four hours, and filtered. The blood films are first fixed in ethyl or methyl alcohol and dried with blotting paper. The stain is diluted with water in the proportion of one drop to 1 c.c. of water, and is poured over the film. Staining requires from five to fifteen minutes, at the end of which time the film is washed thoroughly under a jet of water and is dried.—*Centralblatt für Bakteriologie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended February 10, 1905:

LOSS OF SIGHT FROM DISUSE OF THE EYE (AMBLYOPIA EX ANOPSIA).*

BY D. B. ST. JOHN ROOSA, M.D., LL.D.,

NEW YORK.

FAILURE of sight from disuse of the eye is a subject upon which all authorities in Opthalmology are not agreed, either as to what class of cases come under this head, nor as to all the facts bearing upon the subject. By some writers, of whom the present is one, the term, *amblyopia ex anopsia,* is limited to those cases where use of the eye has been given up, because to use it involves double vision, the maculæ luteæ being no longer in exactly corresponding positions, as is the case in any form of strabismus. By others, cases where the retina is sound, but no image can be formed upon it, and thus it is diseased, are classified under the head of *amblyopia ex anopsia.* Where an opacity of the cornea, lens, or vitreous prevents the entrance of light, there can be no image. The loss of vision here is no proper sense from disuse, but is from shutting out of the illumination. If the obscuration of the media is removed, as in the operation for cataract, the vision becomes at once, with correction of the refractive error, exceedingly good, in some instances perfect. This is amblyopia from obscuration of the ocular media.

In all cases where true *amblyopia ex anopsia* has been fully recovered from, it has been a matter of time. Months or—as in the case I am now reporting—years elapse before the full power of the retina is restored. The two conditions ought never to be confounded. The amblyopia from cataract, either from opacity of the lens, or from an opaque membrane remaining behind, is in no sense analogous to the cases where, in a manner that will shortly be spoken of, the patient may be said to suppress the visual image by a mental action.

The subject of my paper is that form of *amblyopia ex anopsia,* which occurs very temporarily in using one eye for an opthalmoscopic or microscopic examination, while the other eye in disuse—the eye not occupied with the instrument—sees nothing, while the fellow eye is examining the details in the retina, choroid or optic nerve, or those of a pathological or anatomical specimen with a monocular microscope. This is a condition completely analogous to even more, perhaps, exactly like the continued loss of vision in an eye turned inward or outward from the proper line of vision, where the visual power is suppressed. Another form of the same kind of suppression of the image, or rather the suppression of its perception—

* Read at the Annual Meeting of the Medical Society of the State of New York, January 31, 1905.

the image is always formed on the retina, as surely as it is on the sensitive plate of the photographic camera, if an object be placed in front of it—is that which may occur in our daily walks abroad, to any of us, when we are so abstracted by our thoughts that we may look into a friend's face without seeing him. It is still denied on some sides that this condition ever results from strabismus, but that the impairment of vision is congenital, and itself produces the squint. On other sides, it is admitted that it may occur, in part, at least, as a result of the strabismus, but, if so, that the function of the retina never again becomes perfectly normal. In spite of all that has been done in the actual exhibition of cases where the amblyopia has been removed by use and practice, and of the cases where amblyopia has actually occurred after the squint, it has been said, not so long ago, by no less an authority than Priestly

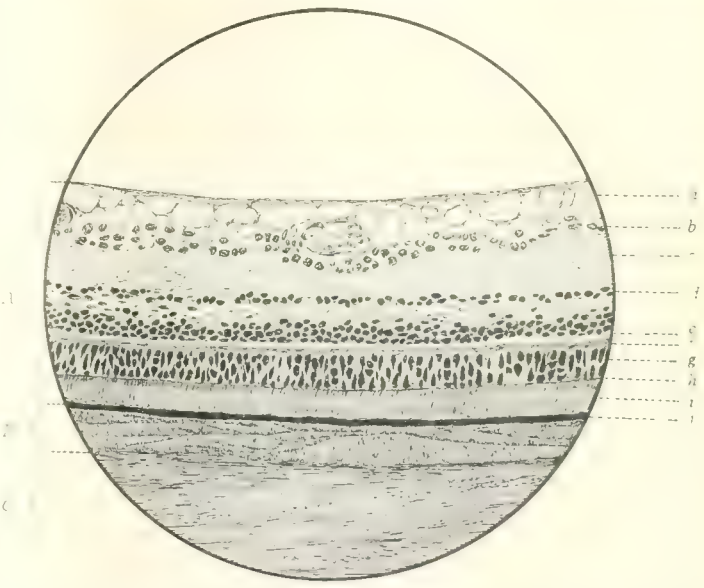

FIG. Retina of a Newborn Child. All the histological elements are fully developed. From a photomicrograph, by Dr. E. L. Oatman. Obj. ⅛, Oc. 1. *A*, Retina; *B*, choroid; *C*, sclera. Principal layers. *a*, nerve fiber; *b*, ganglion cell; *c*, internal reticular; *d*, internal granular; *e*, external reticular; *f*, Henle's fibers; *g*, external granular; *h*, external limiting; *i*, rods and cones; *j*, pigment.

Smith, "there is little evidence to show that an eye which has once acquired good vision, can lose it by squinting." [1] It is in the very nature of things impossible to produce many such cases, but even one, and I, myself, have reported long since one, is enough to show that many more exist.

Priestly Smith then goes on to say, "when this is the case, we should expect to find the faculty recoverable by use." This is exactly just what does occur, as the cases of Agnew,[2] W. B. Johnson,[3] and myself all have shown.

With such statements from high authority confronting us, it is still necessary to report cases bearing upon this subject. They have reached such a number at this writing, that we may question the existence of a true congenital amblyopia. To speak

of the vision of infants as always amblyopic is, I think, to confound the functions of the muscles and the cerebral structure with the anatomical conditions of the rods and cones. The former are certainly in a congenitally feeble condition, but the sensitive plate on which the visual image is formed is as accurate as in childhood. We learn to accommodate and to think, but we are born with retinæ on which as exact an image may be formed, as ever in life.

The accommodative power, the action of the ciliary and internal recto, with the intellect are feeble at birth. The infant has poor fixation power, cannot judge of distances, probably has no binocular single vision on account of this want of development, and it certainly has much advance to make in intelligence, but the retina is as capable of forming perfect images of objects as ever in life. My colleague, Dr. Edward L. Oatman, has many specimens of the infantile retina which prove that the layer of rods and cones is perfect at birth. I cannot for these reasonings accept Priestly Smith's conclusion, that "all eyes are amblyoptic at birth—highly amblyoptic. Those which later reach the standard of normal vision, do so by a process which occupies probably several years." This author (*loc. cit.*, p. 37) has confounded, I think, the power of using the ocular muscles and the brain with the perceptive structure of the retina. If I am right, his deductions fall to the ground.

The case* reported by myself to this society in 1886—a case carefully and critically observed by two of my colleagues, the late Dr. Edward T. Ely and Dr. Emerson, was that of a child with normal vision, who developed convergent strabismus, which was followed by amblyopia from disuse—proves the existence of *amblyopia ex anopsia*. This case is the one quoted by Javal[4] in his treatise on strabismus. If no other had been reported similar to it, it is of itself sufficient to demonstrate that the loss of vision in cases of strabismus is, at least, not always dependent upon a congenital condition. That it ever is, I may add in parenthesis, is, at least, a debatable question. The cases reported by Agnew and Johnson prove that the amblyopia from disuse of the eye, occurring in strabismus, may be perfectly recovered from, and I have other cases in my notebook to prove this. The cases reported by Javal, myself and others show also that even where no accident has occurred to deprive the fellow eye of sight, the amblyopic eye may regain its full power of vision by exercise. Indeed, this may be said to be now generally, but not always, conceded.

These cases are entirely against the contention of Priestly Smith, the retinæ of infants are deficient in visual power. If this be assumed, the amblyopia is merely owing to the fact that the eye, out of the proper range of vision, is not exercised in sight, and does not fully develop. I am not aware of any anatomical or pathological demonstration that converts this theory into a fact. As said above, and as the photograph I exhibit shows, the retinæ of infants, like the cochleæ, are well developed at birth. It is the ocular muscles, not the perceptive apparatus, and perhaps, also, the cerebral ocular centers that go on to full development after birth.

It is because the case I am about to relate supports the proposition that the amblyopia in the deviating eye is functional, and not organic, acquired and not congenital, and also that it may be recovered from perfectly, that I report it. It certainly *proves* that this is true in some cases. Incidentally, it also furnishes evidence that the retinal perceptive layer does not cease to develop, if not used, but requires only to be called into activity.

Case illustrating recovery of sight in amblyopia ex anopsia. Convergent strabismus with amblyopia from early childhood. Operation. Over effect. Second operation, cure of strabismus. Loss of fellow eye from accident. Recovery of sight in amblyopic eye.

John A. R., aged 46, consulted me on the 17th of May, 1900, with the following history: He stated that his right eye, which then turned inwards, was operated on convergent strabismus, when he was about eight years of age, and that divergent strabismus resulted, which was corrected by the writer of this paper, at one of his clinics, in Burlington, Vt., in 1883.

On the 30th of December, 1899, he was accidentally struck in the left eye by a piece of wood. The vision in the injured eye, previous to the accident, was $\frac{20}{20}$. This was the eye which the patient used, and, in fact, was his only dependence. The vision of the right eye has always been very defective. In the right eye the vision is $\frac{20}{100}$, with a cylindric glass of + 4 D. It is $\frac{20}{200}$ without any glass. He has 5 diopters of astigmatism on that side. The cornea of the injured eye is opaque in the lower portion, the pupil is irregular, and filled with broken-up lens matter. There is a small opening in the upper part of the lens. The right eye, which, in early youth, was affected with convergent strabismus, and, as has been stated, after an operation, with divergent strabismus, was now somewhat turned downward, and had eccentric fixation.

I operated upon the left eye for the purpose of removing the lens matter and breaking up the anterior synechia. An iridectomy was performed upon the temporal side, and the lens matter removed. An excellent opening resulted.

I pass from this portion of the case merely by saying that the corneal astigmatism was so much and so irregular that no better vision could be obtained than he had before the operation, $\frac{20}{200}$. I now turned my attention to the amblyopic eye, as being the hope of the patient, if the theory were correct, that it was amblyopic from disuse simply. I found no lesion of the fundus oculi, and it was pronounced to be normal by my associate, Dr. Emerson, and my colleague, Dr. A. E. Davis, who saw the case in consultation, and by myself. After thoroughly testing the patient, he was ordered the following glasses:

R. + 3.50c 130°
L. " 11

A + 4 was added to the cylindric, on the right, for reading. He could not then read ordinary type. The patient was advised to exercise his eyes in reading, beginning with children's primers, and the hope was held out to him that his vision would ultimately be improved. One year and a half afterward his distant vision was not in the least improved, *but he read No 1 Jaeger with his glass.* He was urged to persevere, and he appeared, on October 26, 1904, with his vision in the formerly amblyopic eye, equal to $\frac{20}{30}$, with an appropriate glass, and his corneal astigmatism reduced to 4 D instead of 5 D, as in the beginning. The fixation in the right eye was now central and steady. Vision in the left eye remained as before, $\frac{20}{200}$, but he prefers and wears the glass for the correction and improvement of the sight, over the eye, although double vision can be brought out, and probably exists, under certain conditions, but evidently it does not annoy the patient, who is perfectly content with his condition.

Remarks.—The interest of this case is twofold: first, that a man more than forty years old, after having had an amblyopic eye ever since his early youth, could develop his eyesight to very nearly normal visual power. Second, that the vision for fine type was improved some months before that

*Transactions of Medical Society of the State of New York, 1886. Results of the operation for cenvergent squint.

for infinity,—letters at twenty feet, was improved at all.

The case also shows, in a most interesting way, not only the possibility of relief in such cases, where the good eye is so much injured as to cause a great impairment of sight, but, also, it demonstrates, if any demonstration were needed, the practicability and importance of the treatment first thoroughly carried on by Javal, and widely taught by him, of exercise of an amblyopic eye, for the purpose of removing what turns out to be functional amblyopia.

There certainly are cases where the amblyopia precedes the strabismus, as in membranous cataract, but these are not, as I have already indicated, cases of amblyopia from disuse, but from obscuration, and have no place in this category, nor in this discussion. The cases of a very high degree of astigmatism in one eye, while the other has no defect, are, however, strictly analogous. In some of them it is impossible, with the most exact correction of the error of refraction, to bring the vision up to that of the normal fellow eye. In such cases, we may conclude, I think, not that the retina is not developed, but that it is functionally amblyopic from suppression of the image. Probably all of these cases where the opthalmoscope shows no lesion, would require normal vision, were the fellow eye lost, as in the case just detailed.

This whole subject of strabismus and its cure, with restoration of singular binocular vision, and of normal visual power, is now undergoing a thorough investigation at the hands of some of the best observers in Ophthalmology. Many points hitherto obscured are already cleared up. It is, as a contribution to this gradual elucidation of an important part of our science, that the preceding case is presented.

A REVIEW OF THE RECENT LITERATURE ON THE RELATION OF HUMAN AND BOVINE TUBERCULOSIS.

By DAVID BOVAIRD, Jr., M.D.,
NEW YORK.

It is perfectly understood that while [illegible] been observed between human and bovine tuberculosis, and the possibility of their independence had been considered, practically all authorities until 1901 were agreed in considering them as due to one and the same cause—the growth and development of the tubercle bacillus—and as mutually interchangeable. It was the epoch-making address of Koch at the Congress on Tuberculosis in that year that brought the subject of the relation of human and bovine tuberculosis so prominently before the world as to permit of no delay in determining the question at issue. In consequence, a vast amount of work has been done on the subject within the last three years, and while we are still far from the positive settlement that we would all welcome, enough has been done to determine at least one part of the question and to make it well worth while to review the subject.

In opening the subject it may be well to recall that in Koch's address there were two main points made: first, that human and bovine tuberculosis are different diseases, and that human tuberculosis is not transmissible to cattle; secondly, that bovine tuberculosis is not transmissible to man. On the latter point he was not positive, but he declared that if such transmission occurred at all, it was a very rare occurrence. He estimated the frequency of infection of man from cattle as about equal to that of hereditary transmission, and he therefore did not consider it advisable to take any measures against it.

At the congress at which Koch's report was made several eminent speakers opposed his conclusions. Lister reminded his hearers that before Jenner's time the identity of variola and vaccinia was denied. To-day, said he, we know that vaccinia is a variola that has been attenuated by passage through man. Lister disputed the rarity of primary tuberculosis of the intestine through food infection in children. The entrance for the bacilli must be sought in the intestine, although it is not established that the bacillus must produce a lesion of the mucosa in order to reach the mesenteric nodes. Koch's experiments, in his opinion, required confirmation.

Nocard of Alfort recalled the experiments of Chauveau, who succeeded in rendering calves tuberculous by inoculating them by the intravenous injection of human bacilli. He called attention to the fact that many microorganisms develop slowly on a strange soil, and that their virulence may be increased by passage through other animals.

Bang of Copenhagen took the same standpoint.

McFadyean of London maintained the identity of human and bovine tuberculosis. He cited the efficiency of tuberculin derived from human bacilli in its action upon cattle. He also denied the rarity of primary intestinal tuberculosis, and quoted the statistics of Still of London, which show that 29 per cent. of the tuberculous children in the Great Ormond Street Hospital have such primary intestinal tuberculosis.

Shennan of Edinburgh presented statistics showing that there is 28 per cent. of primary intestinal tuberculosis in children. He quoted Sir Richard Thorne to the effect that while under hygienic regulations and proper milk control lung tuberculosis had diminished 45 per cent. in England; before the era of the control of the milk of tuberculous cattle these diseases had remained stationary, or among children had increased.

Such was the status of the matter at the close of the Congress three years ago. The vital importance of the questions at issue aroused interest and stimulated investigation, so that scientific men in all parts of the world turned their attention to the subject and studies were undertaken to solve its problems.

First, then, as to the proposition that human and bovine tuberculosis are different diseases, and that human tuberculosis is not transmissible to cattle, an enormous amount of work has been done, with, for the most part, harmonious results. It is to be noted that at the time of Koch's declaration there were on record many instances of the successful inoculation of cattle with human tubercle bacilli, notably in the experiments of Chauveau, Bollinger, Klebs, Crookshank, Martin, Nocard, De Jong, and Arloing. Cases of infection of cattle by phthisical attendants had also been recorded by Cozette, Cliquet, Huon, and Bang (see Ravenel). However, numerous experimenters at once set to work to add to the evidence already given, and the results have been such a number of successful inoculations of cattle with human tubercle bacilli as to completely dispose of Koch's first proposition. These successful inoculations have been made by many different observers in many lands. In our own country positive results have been reported by De Schweinitz, Dorset, and Schroeder, and Ravenel; in England by Crookshank, Hamilton and Young and others; in Germany by

Wolff, Fiebriger and Jensen, Orth and Esser. Moeller, however, reports a series of experiments in which he sought to inoculate calves with human tubercle bacilli by feeding, by feeding and intraperitoneal injection, by inhalation and subcutaneous injection, and by injections into the jugular vein. In all these ways he failed to produce tuberculosis in the calves and he therefore agrees with Koch that the human disease is not inoculable in them. Of course, this single negative report cannot offset the numerous other reports to the contrary, but it may serve to emphasize the fact which was made quite clear by the negative results of the experiments on which Koch based his opinion, that it is not easy to inoculate cattle with the human bacilli. It will be noted that most of the successful inoculations have been accomplished either by intraperitoneal, subcutaneous, or intravenous inoculations, rarely by feeding. In fact in some of the experiments it is quite surprising to learn the quantities of tuberculous sputum that were fed to calves without effect, so far as the production of tubercle in the animal was concerned. It is, nevertheless, settled beyond doubt that the human disease can be transmitted to cattle, and the doctrine of the independence of the two affections practically is disposed of. It may, however, be pointed out that there is additional evidence bearing on the latter proposition. The interchangeability of the tuberculins derived from bovine and human bacilli respectively has long been known and constitutes a strong argument for the identity of the bacilli and the two diseases. The two tuberculins, according to Theobald Smith, have the same effects on guinea-pigs, and the bovine tuberculin has been used for the purposes of both diagnosis and treatment in man with the same results as the tuberculin of human origin. In the face of that fact alone, it seems strange that the doctrine of the independence of the two affections should ever have been promulgated, most of all by the very man whose famous discovery of the specific organism had opened the way for the demonstration of the unity of the tuberculosis of man and of the lower animals.

The second proposition, namely, that bovine tuberculosis is not transmissible to man, not permitting of direct experimentation in proof or disproof, has required to be approached indirectly, with results that are naturally less satisfactory or conclusive. Kohler has, however, recalled the fact that as long as twenty years ago Rokitansky, influenced by the supposed antagonism between tuberculosis and cancer, inoculated a number of incurable cancer patients with bovine tuberculosis. Most of these patients lived many months or a year after the inoculation. Some of them developed small, local, quickly-healing ulcers, but at autopsy none of them showed tuberculosis. Those are the only direct experiments on record. Not being able to use human beings for experiment, investigators have resorted to the ancestral family of the monkeys. Cippolina fed one of these animals with milk with which a culture of bovine tubercle bacilli had been mixed and obtained a general tuberculosis with an intestinal lesion. Macfadyean, proceeding on the same line, fed a series of monkeys with bovine tuberculous material and found in a number tuberculous lesions of the mesentary glands and demonstrated the bacilli in them. He calls particular attention to the fact that in none of these cases were the lesions of the glands accompanied by intestinal lesions. Similar experiments were made with human tuberculous sputum with similar results, except that in every instance of successful inoculation intestinal lesions were found. Ravenel, of Philadelphia, has confirmed these results, both as to the inoculation of monkeys, and as to the absence of intestinal lesions in cases of infection by feeding. If then the nearest relative of man in the animal kingdom can be infected with bovine tuberculosis, it becomes highly probable that man himself can be.

Thus far only has the experimenter gone in the direct line to the solution of this question; for further evidence we must turn to the study of observations made under the ordinary conditions of life. It is evident that if the tuberculosis of cattle is transmitted to man, such transmission may take place in one or more of three ways.

1. Persons in close association with cattle may conceivably be infected by inhaling bacilli derived from discharges from the respiratory passages of infected animals. For evident reasons it would be very difficult to prove infections in this way and I know of no evidence that such transmission occurs.

2. Persons handling the infected parts of diseased cattle may be inoculated upon the hands or arms, etc. Hartzell, Ravenel, and others have reported cases of local tuberculous infections on the hands of butchers and veterinarians produced in this way, and Lassar says that in an investigation that he made in the cattle yards of this city he found that 3% of the workmen had such lesions on their hands. So far as the local lesions are concerned there can therefore be no doubt, but there is no evidence that such local infections ever result in the production of general tuberculosis in man, so that these facts have importance only in indicating the possibility of the general infection of man by the bovine bacilli.

3. Persons consuming the milk or meat of tuberculous cattle may be infected by bacilli contained therein. In this possibility we all recognize the vital point of the whole question of the relation of human and bovine tuberculosis and to it therefore we may devote our close consideration.

It is conceded that if bovine tuberculosis is transmitted to man it must be mainly through the agency of milk containing the bacilli. Tuberculosis rarely attacks the parts of the animal used for food, that is the muscles, and even if tubercle bacilli be present in meat, they are either so weakened or destroyed by the processes of cooking as to be rendered relatively harmless. Upon that practically all authorities are agreed. It has been shown that tubercle bacilli may be found in milk, or any products made from it, such as butter and cheese.

The frequency with which tubercle bacilli are found in milk will naturally depend upon the frequency of tuberculosis in cattle. The figures bearing on this subject vary greatly for different countries. In Germany there is careful inspection under government auspices of all cattle slaughtered and the official reports give very accurate information on this subject. From these sources we learn that in Prussia 15.2 per cent. of all cattle slaughtered are tuberculous, in Bavaria 6.3 per cent., and in Saxony 29.39 per cent, while in Bohemia the percentage, according to Ganghofner, is 5.5 per cent. But as already noted it is now generally admitted that only cattle with tuberculosis of the udder produce milk that is dangerous to the consumer. Various investigators (Adami, Rabinovitch, Kempner, and others) have shown that the milk of tuberculous cattle without disease of the udder may be virulent to animals by inoculation, but such authorities as Nocard point out that milk thus proven infective may be quite innocuous when ingested, and maintain that milk dangerous to the consumer is derived only from the cattle having tuberculosis of the udder. According to Bang, in cattle having tuberculosis the udder is involved in not more than 3 per cent. Ganghofner, in his report on the conditions in Bohemia, found

tuberculosis of the udder in only 2.2 per cent. of the tuberculous cows or 0.12 per cent of the cows slaughtered. Considering the matter from this standpoint, it appears, therefore, that the milk of very few cows is capable of producing tuberculosis in the consumer. But we must remember that the great majority of people, especially children, who in the nature of things are most exposed, do not consume the milk of a single cow but the mixed milk of a herd. It is apparent that one cow with tuberculous udder-disease may render the product of a whole herd infective. Some very instructive work along this line has been done, especially in England. Thus Kanthack and Sladen, on examination of the Cambridge supply, found that more than half of the samples tested (9 in 16) proved infective.

Sladen found in the Liverpool milk supply that samples coming from the city stables which were under close scrutiny showed less tuberculosis than those from the country. Thus

Source	No. of samples.	No. showing bacilli.
Town	144	4 or 2.8 per cent.
Country	24	7 or .29 per cent.
Town	228	12 or 5.2 per cent.
Country	67	9 or 13.4 per cent.

E. W. Hope notes the same fact.

Town	422	5 or 1.2 per cent.
Country	490	20 or 4 per cent.

Delepine found 17.6 per cent. of the samples of mixed milk gathered at the railway stations of Liverpool and Manchester virulent by inoculation.

Hope says that after finding in 93 samples of milk, supplied Manchester from the country, 17 containing tubercle bacilli, the city veterinarian visited 16 farms from whch the milk came and on 14 found at least 1 cow with tubercle bacilli in her milk.

It does not, however, follow that all the milk containing tubercle bacilli is capable of producing tuberculosis either in man or animals. If it were, evidently few indeed would escape. Undoubtedly the action of the digestive fluids or of the cells of the body is sufficient to protect from infection by milk, unless the milk contains large numbers of bacilli, or the protection normally afforded by the gastric juice is annulled. Nocard quotes Peuch to the effect that a young pig was able to drink with impunity 4½ liters of a tuberculous milk, a few cubic centimeters of which injected into the peritoneal cavity of a rabbit killed it in a few weeks. Bang has shown that highly tuberculous milk, heated to 70° for five minutes, still kills with certainty rabbits and guinea-pigs when inoculated under the skin or into the peritoneal cavity, but can be drunk in considerable quantities without any danger by animals of the same species. Bollinger and Gebhardt have shown that if the milk of a tuberculous cow is given as a principal or sole nourishment to guinea-pigs, rabbits or cats, all those which take it become tuberculous; but if it is given them diluted in 50 to 100 times its bulk of normal milk, they may consume the mixture for entire weeks with impunity.

So far as our own country is concerned, the information as to the frequency of tuberculosis in cattle is very meager. There is no official inspection of the cattle slaughtered in the abattoirs and the figures obtainable are limited to Clement's observations which give 3% of tuberculous cattle among 5,297 slaughtered in Maryland, and a series of 15,506 cattle inspected in the Brighton abattoir of Boston, of which only 29 or 0.2% were tuberculous. The tuberculin test has, however, been employed on numerous herds in various states with very divergent results. Some herds are found entirely free, others show 15 to 30% of reactions, and in some instances as high as 80 or 90% (Osgood and Pierson).

Regarding the frequency of tubercle bacilli in the market milk of this country, I have been unable to find any reports, but in the nature of things it should be much less than in European countries.

From the facts above set forth it is evident that there must be abundant opportunity, through the presence of tubercle bacilli in milk and its products, for the infection of these consuming them, especially children. The questions naturally arising are (1) what positive evidence is there that such infection actually takes place, and (2) how frequent is such infection or what part does it play in the prevalence of tuberculosis among children or adults.

To return to the first of the questions stated above, namely, what positive evidence is there of the infection of man by means of tuberculous milk or milk products? Such evidence has for evident reasons been sought especially among children. In a previous study of this subject the writer searched the literature of the past fifteen years for reports of cases in which the development of tuberculosis in children had been connected with the use of the milk of tuberculous cattle. 22 such cases were found on record. Since that time I have seen references to a few more cases which had escaped my observation, but the total number would not exceed thirty.

In these cases the facts given may be said to warrant the assumption that the tuberculosis in the children was produced by the consumption of the milk of cattle shown to be tuberculous. It will be recalled that Koch, applying critical analysis to these cases, rejected them all, finding some flaw in the record in every case. For the establishment of his generalization that bovine tuberculosis is not transmissible to man their rejection was of importance, but the ground which he took was undoubtedly extreme. We may admit that some at least of these cases were true cases of infection of children from cattle. To those of us who are interested in the practical bearings of the matter the figures will appear astonishingly small. Not more than thirty cases recorded in the medical literature of both Europe and America certainly would seem to indicate that such transmission of the disease must be exceedingly rare. This view of the matter has been emphasized by developments since Koch's address. In his last utterance on the subject (December, 1902). Koch says that immediately after the deliverance of his address he sent an invitation to the heads of the University clinics in Prussia and also to the directors of the Institute of Pathological Anatomy in Prussia to report to himself any cases of tuberculosis of the intestines, peritoneum, or mesenteric glands in which the onset of the disease might be traced to the use of food-products affected by bovine tuberculosis, either from the histories of the cases or from special facts ascertained. After a year and a quarter not a single case had been brought to his attention.

It may be said without exaggeration that the same message was delivered to the whole scientific world, for the publication of the address was sufficient to set every one interested in the subject looking for such cases, yet with the exception of two cases to which reference will later be made, there has been no response. This failure to produce such cases seems to me very important evidence of their rarity. From facts already set forth it is apparent that there must be opportunity for infection through milk. Considering that from time to time

veterinarians discover herds of cows in which the percentage of tuberculosis (proven by the tuberculin test) reaches 70, 80, or even 90, and that in most instances the milk of these herds has been used regularly for food, it is certainly most strange that some cases have not arisen to which the relationship of the bovine disease to the development of the disease in children could be proven to the satisfaction of everyone. Until such proof is forthcoming it seems to me that very little emphasis can be laid on the danger of tuberculosis in cattle producing the disease in man.

As has just been said two cases have been reported in which the claim is made that the transmission of bovine tuberculosis to children is proven. These two cases are based upon the proposition that there are sufficient differences between the human and the bovine tubercle bacilli to enable investigators to distinguish one from the other, the differences being shown in cultures, in morphology, and in virulence. It is not important for our purposes to go into the details of these differences. In this country they have been worked out by Theobald Smith and Ravenel, and each of these most competent observers has reported a case in which he has demonstrated in the tuberculous lesions of a child bacilli which to him had the characters of the bovine bacillus. So far as the work of these observers is concerned, it is quite conclusive, but we find that other investigators of equal authority, notably De Schweinitz in this country and Von Behring in Germany, deny that the differences between the human and bovine bacilli are sufficint to warrant the attempt to distinguish them from one another. We cannot, therefore, consider the work of Smith and Ravenel decisive of the matter, and until that fundamental question is decided we cannot accept their reports as conclusive of the transmission of bovine tuberculosis to man.

Very recently (August, 1904) Theobald Smith has published a further study of three cases of human tuberculosis in which the infection had apparently entered by the alimentary tract. In all three cases he finds that the bacilli present none of the characters of bovine bacilli, that they are in fact human bacilli and that the infections cannot therefore have been from milk. If, then, the evidence of these observers is accepted as valid, it shows that in the very class of cases which nearly all of us have been ready to admit as milk infections human and not bovine bacilli may be concerned. The total number of cases thus far studied by Smith and Ravenel (five) is too small to warrant any arithmetical calculations as to the frequency with which the human or bovine bacilli will be found in the type of cases concerned, that is the intestinal infections.

A third line of investigation of this question has been carried on in the study of the lesions found in children dying of tuberculosis. From the beginning of experimental work on tuberculosis it has been assumed, and the assumption has been borne out by the bulk of experience, that the oldest or most advanced tuberculous lesions will be found in that tract in which the infection originally entered; that is, if the infection occurred by the respiratory tract the oldest lesions would be found in the lungs or bronchial lymph nodes, if by the intestinal tract, then the oldest lesions will be in the intestines or mesenteric lymph nodes. Infections by the skin, the genito-urinary tract, or the placental circulation are so rare that for our purposes they may be left out of consideration. It was, therefore, thought that by studying the lesions found in autopsies on tuberculous children we could determine the tract by which the infection had entered. A large percentage of cases of primary intestinal infection, it was generally conceded, would indicate that the infection by that tract was frequent. That being established, it would follow from the nature of things that the infecting bacilli had *probably* been taken in with food, and as the disease is most common at the age when cow's milk forms the principal item of food, we would be able to trace the infection back to that source. It was all along understood that there were other possible sources of infection in the intestinal cases than the food, such as dust or dirt carried by the hands to the mouth, but for the sake of simplicity of argument these possibilities were put aside, and the frequency of intestinal infections (primary) was assumed to reflect the frequency of infection from food, that is, cow's milk. A vast deal of work has been done along this line with unhappily discordant results.

In his address Prof. Koch gave the following figures: Ten cases of primary tuberculosis of the intestine occurred in five years among 933 cases of tuberculosis in children at Emperor and Empress Frederich's Hospital for Children. Baginsky never found tuberculosis of the intestines without a simultaneous affection of the lungs and bronchial glands. Among 3,104 post-mortem examinations of tuberculous children, Biedert observed only 16 cases of primary tuberculosis of the intestine

These figures were quoted to prove the extreme rarity of intestinal infections in the tuberculosis of children. Shortly after the publication of Koch's paper the writer published the following table of cases from various sources:

	Total.	Intestinal.	
German,	236	9	4 per cent.
French	128	0	0
English	748	136	18 per cent.
American	369	5	1 per cent.
	1,481	150	

To this table may now be added the following data quoted by Biedert:

Froebelius of St. Petersburg reports observations or 91,370 children, of whom in ten years 18,569 died and autopsies were performed on 16,581. Of tuberculosis there died 416 0.4 per cent. of the total number, 2.5 per cent. of the autopsies. Of the 416 tuberculosis every one had tuberculosis of the lungs, 99.2 per cent. had bronchial node tuberculosis, and 26.9 per cent. had intestinal tuberculosis, so that pulmonary tuberculosis stands to intestinal as 100 to 26.9, with the pulmonary process always primary.

The striking thing about this table is the fact that the cases collected from English literature show a proportion of 18 per cent. primary intestinal infections against 4 per cent. for the German cases, 0 per cent. for the French, 0 per cent. for the Russian, and 1 per cent. for the American. I confessed my inability to understand the difference between the English results and our own at that time. The natural supposition is that the difference must be due to difference of interpretation, that is, that English and American observers have different standards of what constitutes a primary intestinal tuberculosis. I have since satisfied myself that that is not the explanation of the difference. The lesions of tuberculosis are too definite and too well-known to permit the belief that such wide discrepancies in results can be explained satisfactorily as differences of interpretation.

It will, I think, generally be admitted that peritoneal tuberculosis will be most frequent where intestinal infection is most common. In a single morning, in last May, spent in the Hospital for Sick Children in Edinburgh, under the guidance of Dr. John Thomson, the writer was shown eight or more cases of clinical peritoneal tuberculosis in children under

the age of five years. That was a larger number than I could recollect having seen in a rather extensive hospital experience of twelve years in New York City. My impression of the contrast in the incidence of peritoneal tuberculosis in children in Great Britain and our own country has been deepened by some study of the records of the Presbyterian Hospital (of New York) since my return. Among 20,000 cases admitted to that hospital during the last eight years there were just six cases of peritoneal tuberculosis in children under the age of five years. It should be said that the hospital is a general one with a small children's ward, but it can safely be added that no case of abdominal tuberculosis in a child would be declined, and the figures given only confirm the impression of the writer's observations in both dispensary and hospital service in several institutions of the city. The conditions in Edinburgh are said to be fairly representative of conditions throughout Great Britain. This great contrast in the frequency with which peritoneal tuberculosis is seen in Great Britain and in New York, I take it, is simply a reflection of the disparity of the statistics concerning primary intestinal tuberculosis from these sources. These differences are not satisfactorily explained by referring them to corresponding differences in the incidence of tuberculosis among cattle, for we have noted that the same differences prevail between the statistics from Great Britain and from France or Germany, where tuberculosis is quite as common among the cattle as in Great Britain. I am also satisfied that these differences are not to be accounted for on the basis of differences of interpretation. I am therefore led to believe that the differences noted will eventually be explained by the operation of some factors not at present taken into consideration.

This matter of the interpretation of the autopsy findings in children dead of tuberculosis has been rendered still more complex and puzzling by the developments of the last few years. In Germany Hueppe and Heller have called in question the statement that cases of primary intestinal infection are rare there. Councilman, Mallory and Wright have done the same thing in this country, and curiously enough Heller's protest as well as that of the American observers have been based on the autopsy findings of children dead of diphtheria. In these they find tuberculosis common and in the tuberculous cases both find approximately 37 per cent. of primary intestinal infections.

Ganghofner of Prague contributes a reply to the observations of Heller and Councilman, Mallory and Wright, showing a percentage of 37 of primary intestinal tuberculosis in the cases of tuberculosis found at autopsy in fatal cases of diphtheria. Among 972 children dead of infectious diseases (diphtheria, measles, scarlet and variola) he found tuberculosis in 252, 25.9 per cent. Of these 252, 179, or 71 per cent., had tuberculosis of the lungs and bronchial lymph nodes; 51 cases in addition to the tuberculosis of the lungs and bronchial lymph nodes showed intestinal tuberculosis, either of the intestine itself or of the mesenteric lymph nodes, frequently also tuberculosis of other parts. So far as a primary intestinal tuberculosis is concerned, the results were as follows:

515 cases of diphtheria, no case of primary intestinal tuberculosis.

176 cases of measles, 2 cases of tuberculosis of the mesenteric lymph nodes alone.

219 cases of scarlet, 1 case of tuberculosis of the intestine alone and 1 of the mesenteric lymph nodes.

62 cases of variola, no case of primary intestinal tuberculosis.

In the 972 children dead of acute infectious diseases, there were therefore 4 cases of primary intestinal tuberculosis, or 0.4 per cent. Of the 253 cases of tuberculosis, the 4 cases constitute less than 2 per cent. of primary intestinal tuberculosis. Ganghofner then gives an interesting table comparing the results of the observations of Councilman (Boston), Baginsky (Berlin), Heller (Kiel), and himself (Prague).

	Kiel.	Boston.	Berlin.	Prague.
Number dead of acute and infectious diseases,	714	220	806	973
Number of cases of tuberculosis,	140	35	144	253
Percentage of the dead,	19.6	16	17.8	28
Number of cases of tuberculosis through infection of the digestive tract,	53	13	6	5
Percentage of the dead,	7.4	5.9	0.7	0.5
Percentage of the cases of tuberculosis,	37.8	37.1	4.1	2

The great difference between the figures obtained at Kiel and Boston from those of other observers Heller has attempted to explain on the ground that tuberculosis of the mesenteric nodes especially has been overlooked by the latter. Ganghofner shows that he has taken precautions that render that hypothesis inapplicable to his results.

These radical differences between the results of skilled observers in different parts of the same country are not, as I have already said in another connection, satisfactorily accounted for either on the basis of different interpretation or by differences in the frequency of tuberculosis among the cattle, and they are likely to be explained in the end by the operation of some local factors not at present taken into consideration.

The difficulty of interpreting the results of these reports of autopsy observations in children has been further enhanced by some very important work done by Ravenel.

He attacks the common conception that if infection occurs through the alimentary tract the tuberculous lesions should be found either in the intestines or in the mesenteric nodes or both. During intestinal digestion, he says, there is a constant current from the intestine to the mesenteric glands and thence up the thoracic duct to the venous circulation. Any tubercle bacilli which may have gained entrance into this stream are carried almost immediately into the lungs and deposited there by election. He cites the work of Dobroklonski to prove that tubercle bacilli may pass the intestinal wall without producing local lesions. In their laboratory work they have, Ravenel says, been struck by the extensive involvement of the lungs in animals infected by feeding and the coincident slight injury to the intestine. Indeed, in some animals it has been quite impossible to detect any involvement of the intestine whatever, and at the reading of the paper he exhibited the viscera of some of the animals illustrating this point.

Having seen these specimens of Ravenel's, the writer must admit that similar conditions in a child he would have interpreted to mean that the infection had been conveyed through the respiratory tract. If confirmed by further experience, these observations will undoubtedly invalidate the interpretation that has been placed upon the results of post-mortem observations in children. To me, however, it seems to be unwise to allow the results of one observer to overthrow the established interpretation, until those results have received confirmation from others. It has long been known that animals could be infected with tuberculosis through the intestine without producing an intestinal lesion. The observations of

Cornil and Dobroklonski established that; but if the intestinal lesion failed, the lesion of the mesenteric nodes still indicated the tract through which the infection had come. This has been long recognized, and we may note that this is exactly what Macfadyean found in his experiments on monkeys and calves, the very animals in which Ravenel's unusual results were obtained, and we may also quote two of the conclusions which Hamilton and Young give as the outcome of their recent experimental studies:

1. That the organs most affected are those in immediate connection with the part operated upon (they are speaking of infection conveyed by feeding the animal with tuberculous material, by subcutaneous inoculation upon a peripheral part, by respiring a spray containing the bacilli, or by injection into the venous system).

2. That the lymphatic system is constantly involved in the resulting tuberculosis.

Despite the discordant results noted above, it seems to me that we can still safely say that the greatest weight of evidence is against frequent infection of children through the intestine, that is through food, and that we cannot, therefore, consider that tuberculous milk is frequently the means of conveying the infection.

The most conclusive evidence in support of this view has, however, come from comprehensive studies conducted in certain parts of the German Empire concerning the relationship between the frequency of tuberculosis in cattle and among human beings in areas in which there are large numbers of cattle and where milk and its products are largely used as articles of food. The exact statistics which are obtained by the authorities upon these subjects render these studies very convincing.

Biedert has conducted an investigation along these lines which he thinks has all the value of an experiment in feeding men bovine bacilli.

Swabia, according to statistics, has the greatest number of cattle, average cattle tuberculosis, and moderately high rate in man. Upper Bavaria has an average number of cattle, the lowest rate of tuberculosis among the cattle, and relatively high rate among men. Lower Bavaria has an average number of cattle, the highest tuberculosis rate among the cattle, and the lowest among men. The Upper Palatinate has the lowest number of cattle, the highest tuberculosis rate in cattle, and a high rate for man.

Of the eight Bavarian provinces the four having the greatest number of cattle are the lowest in human tuberculosis excepting Upper Bavaria, where, in opposition to Oberfranken, there are four cities with very high mortality from tuberculosis, while Oberfranken has only one such city. Cattle tuberculosis is therefore without influence and harmless to man. On the contrary, the large dairy industry increases the prosperity and the general consumption of milk improves the nutrition of the people.

Ganghofner has also undertaken a study of the relation of the deaths from tuberculosis among men to the number of cattle found to be tuberculous in the abattoirs of his native land, Bohemia. His study is based on official reports of recent years. The mortality among men from tuberculosis in Bohemia is calculated for each 10,000 inhabitants, and on the average amounts to thirty-five.

The percentage of tuberculosis in cattle found in the abattoirs averages 5.5 per cent. Of the tuberculous cows 2.2 per cent. had tuberculosis of the udder, a fact of considerable importance, inasmuch as it is now generally admitted that only the cows having udder tuberculosis are likely to show sufficient numbers of bacilli in the milk to be really dangerous. Not to weary you with the details of the study, suffice it to say that, exactly as Biedert found, Ganghofner can discover no relation between the number of human beings dying from tuberculosis and the number of tuberculous cattle in the various districts (85 in all are considered) of Bohemia. Neither is there any relation between the human mortality from tuberculosis and the number of cows found to have tuberculosis of the udder. Ganghofner sums up the results of his study in the following words:—The possibility of the transmission of bovine tuberculosis to man must be admitted, for so long as it is possible to infect cattle with human bacilli, it is reasonable to assume that the reverse infection is possible. There is, however, no evidence that such infection is frequent. Neither his pathological observations nor the statistical studies on the relation of human and bovine tuberculosis indicate that the consumption of food containing bovine tubercle bacilli has any considerable importance for the production of tuberculosis in man, more particularly among children.

The practical purport of this paper may be briefly summed up in the following conclusions:

1. Human tuberculosis can be transmitted to cattle, but with difficulty, and it seems highly improbable that such transmission plays any great part in the production of the disease among cattle.

2. Bovine tuberculosis can be transmitted to man, but the evidence that such transmission occurs under ordinary circumstances is extremely scanty and it is highly improbable that such transmission plays any important part in the spread of the disease in man.

THE ADVANTAGES OF PERFORMING CAPITAL OPERATIONS IN SELECTED CASES WITHOUT ANESTHESIA.*

By J. J. BUCHANAN, M.D.,
PITTSBURG, PA.,
SURGEON TO MERCY HOSPITAL

THE beneficent effect of ether and chloroform in the production of general anesthesia during surgical operations has received its due meed of praise from countless pens and tongues for more than half a century. To add a single word of appreciation of the blessings of anesthesia would be more than superfluous—it would be presumptuous. The eagerness, however, with which local anesthesia with cocaine and its congeners has been seized on by surgeons, is a strong indication of the feeling that general anesthesia is not always safe.

It will be readily admitted that the use of cocaine and similar drugs for local anesthesia has its limitations, among which are, (1) the extremely limited quantity of an efficient local anesthetic which can be used with safety, (2) the uncertainty of securing satisfactory anesthesia, (3) the poisonous effects so often resulting from quantities usually found to be safe (irregular action or idiosyncrasy), and (4) inapplicability to the viscera and other deep-seated structures.

The present generation of surgeons, having always had ether and chloroform at their command, have apparently disregarded the advantages to be derived, in certain cases, by operating without these agents. Having but little experience in this direction, they have been prone to take an exaggerated view of the suffering produced by operation and to underrate the willingness and endurance of the patients.

The opinion here expressed as to the extreme infrequency of important operations without anesthesia is based on a critical examination of the titles in the first and second series of the Index Catalogue of the Library of the Surgeon General's office, of the first and second series of the Index Medicus, of general impressions of recent surgical literature, and personal communication with surgeons of large experience.

The indications which I have followed for operating without anesthesia are the following: (1) Profound septic infection; (2) severe collapse from loss of blood and shock; (3) fecal vomiting with liability to drowning during operation or aspiration pneumonia subsequently; (4) collapse or compression of lung with liability to respiratory failure; (5) obstruction of the esophagus; (6) advanced kidney disease with liability to anuria; (7) ease of performance with minimum of pain.

These indications are sufficiently clear to recommend themselves without much comment, for I cannot believe that there is any surgeon who has not had the painful experience of losing patients during or after operation, under these conditions, whose lives would have been saved had anesthesia not been employed. Without going into wearisome detail, I may be permitted to cite a number of operative procedures which I have carried out in recent years, most of them having been done in numerous instances. The majority of the operations to be mentioned may fairly be termed "capital;" but some are of a minor nature.

1. *Appendectomy* in certain acute cases attended with profound sepsis. All surgeons have observed the extreme depression following abdominal operations under general anesthesia, in patients already suffering from acute sepsis. The vital resistance is diminished by anesthesia and the organism falls an easier prey to the bacteria and their toxins by which it is already poisoned. With our present more conservative practice regarding operation in acute appendicitis, where spreading peritonitis has supervened, the indication for appendectomy without anesthesia is rare. Occasionally, however, it does present itself and should then be recognized.

2. *Amputation of limbs,* including mid-thigh, leg, upper arm, and forearm. These amputations have always been performed in cases of severe collapse from loss of blood and shock, when even the largest amounts of intravenous saline infusion (4 to 8 quarts in six hours) have failed to produce satisfactory reaction. The treatment of such cases has been outlined at greater length by the writer in a paper read before the National Association of Railway Surgeons at St. Louis on April 3, 1896.*

3. *Resection of shoulder-joint* for crushing injury; the indications being the same as in the amputations just cited.

4. *External perineal urethrotomy* without a guide for ruptured urethra from crushing injuries. The indication in these cases has been circulatory depression from urinary retention and extensive extravasation of blood and urine into the cellular tissue.

5. *Exploratory laparotomy with examination of viscera* for suspected intraperitoneal injuries. The indication in these cases is the extreme collapse present, in which it is impossible, without exploration, to distinguish between nervous shock, intraperitoneal hemorrhage and beginning peritonitis from extravasation of visceral contents.

6. *Laparotomy for relief of intestinal obstruction by bands;* 7. *Inguinal colostomy* in cases of obstruction; 8. *Herniotomy* in strangulated umbilical, ventral, inguinal, and femoral herniæ; 9. *Intestinal resection* in gangrenous hernia; 10. *Radical cure of umbilical hernia* in strangulated cases by Mayo's overlapping method. The indication in the five classes of cases last mentioned has been the presence of vomiting, often fecal, and the consequent danger of drowning at the time or aspiration pneumonia afterward.

11. *Rib resection for empyema.*—The danger of general anesthesia when respiration depends on one lung is well recognized and furnishes the indication in these cases.

12. *Gastrostomy.*—The mortality hitherto in this operation has been generally from pneumonia, probably from inspiration by the anesthetized patient of secretions which could not be swallowed owing to the obstruction of the esophagus.

13. *Suprapubic cystotomy;* 14. *Prostatectomy.*—In both of these operations, when done for enlarged prostate, the kidneys are in such condition that anuria frequently results from the use of general anesthesia.

15. *Tracheotomy.*—The danger of flooding the trachea with blood during general anesthesia in this operation has long been recognized and many surgeons have advised that anesthetics be withheld for this reason.

16. *Craniotomy* or trephining with chisel and mallet for depressed fractures of the skull.

17. *Evacuation of intraperitoneal abscesses* (usually appendical) by the muscle-splitting method; 18. *Ligature of femoral artery* for popliteal aneurysm; 19. *Wiring fractured patella* through an open incision into the knee-joint. In the last three classes of cases, the operations have always been done because the patient has been more willing to

*Paper read at meeting of Medical Society of State of Pennsylvania, September 20, 1904.

*Railway Surgeon, 1896, No. 3, p. 241

endure a moderate amount of pain than to suffer the discomfort of general anesthesia with its resultant nausea.

The operations named by no means exhaust the list of those which the writer has performed without anesthesia; but they are sufficient to indicate the class of procedures to which this method may be applied with safety and satisfaction.

Now, with reference to the amount of pain caused by operations of the nature of those just mentioned, I am sure that it is much less than would be expected without experience. It is never such as to call for the least restraint in patients who have reached the age of reason. It is rarely such as to cause the patient to flinch in the slightest degree or to interfere with the progress of the operation. It is rarely sufficient to cause the patient to make any outcry.

The various tissues of the body differ greatly in sensibility to pain. The integument, as is well known, is quite sensitive, and, for this reason, the primary incision should be made quickly and with a sharp instrument. Under these circumstances, patients seem to suffer but little more than by the introduction of the needle for local anesthesia. The use of sharp retractors is comparatively painful and these instruments should be avoided whenever they can be replaced by blunt retractors. Nerve trunks are, of course, sensitive, and the pinching of nerve filaments with forceps causes acute pain. With some attention to this point of removing any forceps that is seen to cause pain and avoiding pressure on the nerve trunks, but little trouble will be experienced from this source. The parietal peritoneum is exquisitely sensitive and its edges in the incison should not be clamped unnecessarily. The peritoneal viscera are not sensitive. The stomach and intestines may be cut and sewed without causing pain, but traction on their attachments gives rise to a dull pain, which is much complained of if the traction is strong. Separation of recent peritoneal adhesions causes but slight pain. Chiseling and drilling of bones causes but little pain, usually none whatever. Contrary to the common belief, I have not found that the blows of the mallet in chiseling the skull give rise to any shock, depression, or mental confusion and this is an observation which I have made on many occasions.

Amputations are made quickly, but without undue haste, and give rise to surprisingly little pain.

In conclusion let me call attention to certain conditions necessary to success in operating without anesthesia:

1. There should be a good and sufficient reason for withholding the anesthetic.

2. The consent and cooperation of the patient must be secured. With proper presentation of the matter, this can almost always be accomplished. Even little children, foreigners who must be approached through an interpreter, and delirious patients are amenable to the necessary arguments in many instances.

3. No restraint whatever should be employed except in the case of children who have not yet reached the age of reason.

4. There should always be given the promise of an anesthetic in case the pain should prove unendurable. Fulfilment of this promise is rarely necessary.

5. An occasional rest, at the request of the patient, during a prolonged operation, is always advisable.

6. A full understanding of the nature of the operation should be had with adult patients, and information from time to time as to the progress of the operation has a marked effect in promoting their endurance.

7. A word of warning to the patient, when painful parts of the operation are coming, such as the primary incision, cutting the parietal peritoneum, and the section of nerve trunks, will be advantageous.

8. As a rule it is well to screen the field of operation from the patient's view.

Finally let me say that it is not within the surgeon's province to inflict unnecessary pain, but that his primary aim is to save life; and, when the induction of anesthesia appreciably increases the danger of operation, his courage should rise superior to the natural pity which inspires him and he should give a willing patient every additional chance for recovery.

FOUR CASES OF CHANCRE OF THE LIP.

By CHARLES MALLORY WILLIAMS, A.B., Ph.B., M.D.
NEW YORK,
CLINICAL ASSISTANT, NEW YORK SKIN AND CANCER HOSPITAL.

Notwithstanding the enormous number of observations to the contrary, the general opinion still regards syphilis as an exclusively venereal disease, and as long as this opinion holds sway, so long will cases of extragenital infection be of interest and of value. Of course we all recognize the possibility of such occurrences, but in ordinary history taking, how often is the possibility overlooked! And if this tendency is common in the profession, it is almost universal in the general public, to whom we must look for support in all efforts at prevention. If the mass of people can be brought to understand that every case of syphilis is a menace, not only to those with whom he may hold sexual congress, but also to all whom he meets in his daily life, they may be persuaded of the necessity of some sanitary regulation of these patients. That extragenital chancres are by no means rare is shown by the fact that the four cases here described all applied within a period of four and one-half months.

The modes of transmission are innumerable. In Bulkley's very thorough monograph, "Syphilis Insontium," may be found well authenticated instances of the most curious and unexpected carriers of the infection, as well as of the more common, such as pipes, knives, forks, towels, and, most frequent of all, the lips. Still more common than the cases in which the contagion can be traced to its source, and more important also, as showing the wide diffusion of the disease and the danger of infection from apparently harmless objects, are those whose origin is entirely obscure. The cases here recorded belong to the latter class. They occurred in the service of Dr. L. Duncan Bulkley at the New York Skin and Cancer Hospital, and to him I am indebted for the privilege of reporting them.

Case I.—Female, single, aged 20 years. She denies absolutely all kissing on the mouth, and does not know of the existence of any disease of the mouth or lips among any of her friends or acquaintances. About the end of May, 1904, a sore appeared on the right side of the vermilion border of the upper lip, and a little later another formed on the left side of the lower lip. Both grew worse in spite of local treatment, and when first seen, July 1, 1904, there was on the right upper lip a shallow ulcer, with a broad, cartilaginous base. On the left lower lip was a somewhat similar ulcer, but smaller, and with less induration. The submaxillary glands were enlarged and there was a mucous patch on the right tonsil and a macular syphilide over the lower chest and abdomen. The patient complained of headaches,

insomnia and weakness. It was at first thought that the case might be one of double chancre, but the progress of the lesion on the lower lip indicated that this was probably an inflamed mucous patch. After two weeks of mercurial treatment, the constitutional symptoms and the macular eruption had gone, and the lower lip was nearly well, while the upper lip still showed marked induration.

Case II.—Male, single, aged 36 years. The patient is a man of loose habits, but was able to keep track for several months after the development of his disease, of all the women with whom he had connection, and so far as he could tell, all of them remained well. He seldom smokes a pipe, and never any but his own. In March, 1904, a sore developed on the middle of his upper lip. It lasted about two weeks, and was followed by an eruption on the trunk which disappeared under treatment with mercury by the mouth. In November, 1904, about six weeks after stopping treatment, there was a very severe outbreak of papulopustular syphilides, which yielded quickly to mercurial inunctions.

Case III.—Male, single, aged 29 years. His habits are loose, but he denies ever having had a chancre, and there is no sore or scar on his penis. During the latter part of the summer, up to the second week in September, 1904, he spent much of his time on a yacht and smoked frequently the pipes of various men. One evening, early in October, he had a severe chill, for which he took ten grains of quinine and some whiskey.. The chill was followed by fever and profuse sweating, but was not repeated, though the patient felt very sick for two days, and has had chilly feelings at intervals ever since. Very soon after this he noticed a sore like a fever blister at the left angle of the mouth. This enlarged until November 11, when it was about one-third of an inch in diameter and covered with a thick, dark crust. The base was indurated, but the induration did not extend beyond the border of the crust. There was a fissure extending one-quarter of an inch onto the buccal surface of the left angle of the mouth. The tonsils and fauces were congested, but no mucous patches were visible. The glands under the left side of the jaw were enlarged. There was a macular syphilide over the entire body, and on the left arm a typical scaly papule. He was given tablets of hydrargyrum cum creta, and a week later the chancre was healed over, though the induration persisted, the congestion of the fauces was gone, and the eruption was fading.

Case IV.—Male, single, aged 31 years. The patient is a man of loose habits. He denies any sore on his genitals and any previous eruption, and he never observed any eruption on the face or lips of any of the people with whom he came in contact. About two weeks before the appearance of his chancre he smoked the pipe of an acquaintance who had some sort of an eruption on the back of his neck. In May, 1903, the patient noticed a crack on the right side of his lower lip. It soon grew to a small ulcer, and then remained stationary, in spite of various local applications, for about six months. At the end of that time it was burned out, probably with the actual cautery, after which it began to heal from the edges. A little later he suffered from severe pain in the right shin, worse at night. The physician whom he consulted for this pain told him that he had a sore in his mouth. He took medicine and rubbed salve on his leg regularly for six weeks, by which time the lip was healed and the pain was gone. In the spring of 1904 a sore formed on the upper lip, near the left angle of the mouth. This spread, in spite of local treatment, till September, 1904, when he had on the left upper lip a tubercular syphilide about one-quarter of an inch broad and three-quarters of an inch long, with shallow ulceration in places and some loss of tissue. The lesion improved immediately under mixed treatment.

In the first case, the most careful questioning failed to discover any possible source of contagion. The patient was infected apparently, by some accident which might happen to any of us. The location of the initial lesion was somewhat unusual, being on the upper lip, whereas in 30 original cases of chancre of the lip in women, reported by Bulkley (loc. cit.) 21, or 70 per cent. were on the lower lip.

In the remaining cases the mode of infection was probably by kissing, though in the third and fourth a pipe may have been the carrier of the contagion. In the last case it is interesting to note also the long duration of the chancre—six months, according to the patient—and the fact that it remained so long unrecognized. Not till he consulted a second physician for the bone pain was the correct diagnosis made. During all that time, every drinking utensil, every fork or spoon he used, every pipe he smoked, every towel he used upon his face, every barber shop he visited, became a possible means of the spread of the disease. We may never know how many innocent people were infected by this one man, himself unconscious of the danger; but the opportunities for transmission were certainly varied and numberless. It is instances like this that make us wonder, not that extragenital infection should sometimes occur, but that it is not even more common.

616 Madison Avenue.

AN UNUSUAL CASE OF PELVIC ABSCESS.*

By W. H. COE, M.D.,
AUBURN, N. Y.
PATHOLOGIST AUBURN CITY HOSPITAL.

In this present day there are few cases of abdominal or pelvic growths which are not amenable to relief or palliation by surgical treatment. So great has become the safety of exploratory incisions for inspection of possibly infected areas, that it is a procedure commonly resorted to; and it is an unusual case the diagnosis of which is not made apparent to direct visual and manual inspection. The case to be described belongs to this class.

Mrs. B., age 35, primipara, was taken with a miscarriage at the third month. When the writer was called during the absence from town of the family physician, he found her with labor pains; and the fetus was born with no other complication than that of retained placenta, owing to contraction of a rigid cervix. This was removed with placental forceps, and the cavity was washed out with boiled water. When the patient became more at ease, the history was elicited. For about ten days previous to my first visit she had been suffering from chills and fever. The family physician had also found her in the same condition; but these signs had not been distressing, and required little treatment. For a week following the miscarriage, he took charge of case until, on his absence from town, I was again called, and continued afterwards in the case.

At this time the patient had a temperature of 103°, followed by a sweat and a dropping of the temperature to about 99°. Then followed a comfortable interval in which she slept, or felt calm nd easy. The fever began gradually to rise again, until it reached its climax with corresponding increase of restlessness and discomfort. The general picture was that of blood poisoning, and indi-

*Read before a meeting of the Auburn City Medical Society.

cations pointed to infection at some considerable time previous to the miscarriage; the cause was unknown, all questions upon that point resulting in nothing. In a few days the temperature at its height, reached 106°; and the grave outlook rendered her removal to the hospital necessary.

Vaginal examination showed the uterus soft and movable, with no tenderness. High pressure at the right of the uterus showed a hardness and resistance, at the tip of the examining finger, and this elicited much suspicion. A diagnosis was made of pus absorption from some source, and the question arose as to what should be done.

The treatment consisted of nourishing diet, cold packs, when the temperature reached 103°, varying in vigor in proportion to the height of the fever, and always brought much comfort and relief to the patient. Medication at first consisted of unguentum Credé, one drachm, rubbed into the skin twice daily. Slight improvement was noticed at first; but, this failing, an antiseptic containing carbolic acid was added, being injected hypodermically each day, until the physiological effect of the acid became apparent by the smokiness in the urine.

This alternating round of chill, fever, and sweat continued day after day, sometimes better, sometimes worse, with corresponding alteration of hope and despair on the part of watching relatives. At best the temperature when at its maximum reached only 102°; and at worst it ran even to 107° in axilla. The interval of comfort was marked by the patient sleeping and recuperating with clear mind, and unflagging courage, ready for the ensuing fever which followed with unfailing persistence.

The hopeless outlook through this long illness of over a month made surgical interference seem needed, even though the indication was obscure, and during this time council was had three times to determine its advisability. The hardness in the right broad ligament continued. The question arose whether an exploratory incision above with inspection followed by puncture below, might not reli[illegible] if a pus pocket could be found. The friends were ready for operation, if necessary, but opposed the idea in general, for a relative having died in hospital following an operation of last resort, they were strongly prejudiced against another. Operation under prevailing conditions was, therefore, decided against, and the wisdom of this was made apparent at the autopsy.

The illness continued with unabated intensity—chill, fever, and sweat, with gradually approaching physical exhaustion of patient. The picture during the last week was distressing in the extreme. The face was drawn and anxious. The skin was brown, and emaciation was marked, but the mind was clear, until the last few days, when delirium, pain, and labored breathing obscured both mental and physical senses; and the curtain was finally drawn before a scene which had exhausted the emotions of the friends and the resources of the physicians.

With the husband's consent, an autopsy was performed to determine the source of the infection. The abdomen was opened, and inspection made of the pelvis. In general appearance the parts were normal, the uterus was of usual size, freely movable, and without adhesions. The anticipated pus pocket above the right broad ligament was not there, the broad ligament itself was stiff and resisting, but when taken between the thumb and finger it showed little thickening. Had this been an exploratory incision in life, the abdomen would have been closed without anything more being discovered, and the patient would have died, and the friends would have said, as in the other case, that the operation had been instrumental in her death.

However, in continuing the autopsy, the uterus was to be removed for inspection of its interior. On cutting around it, and reaching the right broad ligament, its folds were severed, and a little pus oozed out. Inserting the finger in the opening, the hole was followed outward and backward to the wall of the pelvis where, extraperitoneally was found a considerable cavity lying against the bare muscles and tendons. This contained a greenish slimy pus, and extended backward as far as the sacrum, and showed that the severity of the infection from which the patient suffered was based upon this large area of pus absorption. This cavity was strictly pelvic, and no trace of bony caries could be found.

Examination of the interior of the uterus showed nothing except a few drops of yellow pus in the cervix. Bacteriological examination of this pus showed staphylococci; examination of pus from the abscess showed old broken-down corpuscles, and no bacteria. The radically different results of the two examinations was striking, and raised the doubt if the source of the pus in the two cases could be the same. The present belief of the writer is that the original source of the infection was from the uterus.

While there is a saying that desperate situations may require desperate remedies, it does not follow that it is always wise to use them. A vaginal puncture in the right direction might have reached the pus; but the indications in life were insufficient to show where to direct it, and only the autopsy finally revealed the nature and location of the cause of death.

EAR COMPLICATIONS OF SCARLET FEVER, AND THEIR TREATMENT.*

By HERMAN JARECKY, M.D.,

NEW YORK

VISITING OTOLOGIST, HARLEM HOSPITAL; EYE, EAR AND THROAT SURGEON, SYDENHAM HOSPITAL; ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL, ETC.

THE frequency of ear complications during the course of scarlet fever and their serious consequences, lead one to regard the subject as of the greatest importance to the general practitioner. This opinion is intensified by a study of the statistics. In 1880 Burkhardt-Merian[1] reported of 4,309 cases of deaf mutism collected from various authorities and countries, 445 to be from scarlet fever, about 10 1-3 per cent. He himself speaks of 85 ear cases due to scarlet fever, of which 72 were bilateral.

In 1898 at the Willard Parker Hospital[2] of 386 cases of scarlet fever admitted, otitis complicated 77, and in 33 of those both ears were affected; and in 1899 of 387 cases of scarlet fever, otitis developed in 43 with 23 double. Thus, out of 773 cases, nearly 20 per cent. were complicated with otitis, and of these one-half presented the sad spectacle of a bilateral otitis. In 1901 Le Marc'hadour[3] reports that of 339 cases of scarlet fever, 36 developed otitis—a percentage of 10.65 per cent.

Various epidemics vary in the number of complications and of the severity of the disease. The otitis may be severe in a mild case and vice versa. Each ear may be attacked separately or both simultaneously with different degrees of intensity.

In considering the etiology we must conclude the ear complications are due to one of the following causes: (1) toxins of the disease; (2) extension from the throat; (3) general weakness.

*Read at a meeting of the Harlem Medical Association, November, 1904.

1. Toxins undoubtedly cause those cases (*a*) which occur with the general intoxication of the system at the outset of the disease; (*b*) in which the labyrinth is affected without the middle ear being attacked and cases of panotitis; (*c*) at the period of desquamation; all acute symptoms at this time have usually disappeared, that is during the second and third weeks of the disease; at this time nephritis occurs which is certainly septic; (*d*) the virulence and destruction which follows as a rule in this disease can be accounted for in no other way.

2. Extension from the throat along the Eustachian tube occurs from the intense pharyngitis, pseudomembranous, and diphtheritic angina. Adenoids favor this form.

3. General weakness as in all debilitating diseases predisposes to an otitis. It has also been suggested that in the general wasting, the fat at the opening of the Eustachian tube is absorbed, thus easily allowing the entrance of infection.

Bacteriology places the streptococcus pyogenes[4] as one principally found in the aural discharge. There are also the staphylococcus pyogenes albus and aureus. Fraenkel's pneumococcus or diplococcus, and Friedlander's pneumobacillus. The Klebs-Loeffler bacillus is found in later cultures and seems to develop when the system is somewhat weakened.

The streptococci[6] undoubtedly do the mischief in the destruction of bone and the formation of sinus thrombosis, while the diplococci are responsible for epidural abcess. Therefore, by many the streptococci have been considered the germs of scarlet fever and the curative serum adopted has been the antistreptococcus. But no specific organisms have been isolated thus far; one set may be active for a time and then may be replaced by another or a mixed infection may exist.

External Ear.—The general rash of the disease affects the auricle, causing a dermatitis. Sometimes the canal becomes swollen, causing some discomfort. These usually pass away with the acute symptoms of the disease.

Middle Ear.—The inflammation of the middle ear is distinguished by two varieties; the catarrhal and the purulent. The catarrhal variety is as a rule mild. The tympanum usually contains more or less serous exudation mixed with mucus. The drum membrane is somewhat congested, but very often of a peculiar bright appearance, and the level of the exudate can usually be seen. The exudation consists of mucus, some pus, and epithelial cells. If the process is severe, the membrane loses its luster and may bulge.

The purulent type, which is the more frequent, is usually severe. The congestion generally begins in the upper part of the membrane, extends down along the handle of the malleus. This is quickly followed by a transudation of the fluid elements of the blood and a migration of the white blood cells. Thus a general edematous condition exists, choking off the circulation and necrosis follows. The membrane is completely bulged out and may perforate and is soon destroyed to a great extent. The secretion varies in character and quantity, at first seropurulent, later it becomes decidedly purulent. The ossicles become carious. The pus may burrow between the mucous membrane and the bone.

A small proportion of cases recover at the termination of the active stage, others degenerate into a condition of chronicity, which is either characterized by more or less abundant secretion, or else marked by a hyperplasia of the mucous membrane with adhesions between the various parts. The first variety will have more or less exposed necrosed bony tissue with frequently a foul odor and granulations or polypi will develop.

The examination of the tympanum is easily accomplished, and should be a routine measure. The largest speculum possible should be used. In the adult, draw the auricle upwards and backwards, in children backwards and in infants downwards and look upwards. To examine infants' ears quite a little practice is required.

The mastoid and the lateral sinus may become involved by the backward extension of the process.

The *internal ear* may become affected through the fenestræ connecting with the labyrinth.

Meningeal and brain complications may arise, especially in children on account of the dehiscence which exist above, and from the intimate connection of the dura mater with the lining membrane of the tympanum.

Thrombosis of the jugular bulb may arise from the extension of the inflammation through the floor of the cavity.

Any continued unaccounted-for temperature, and during the second or third week any rise in temperature should attract attention to the ears. The attack may be accompanied by pain that may be slight or so severe as to lead to convulsive attacks and even coma. The temperature varies from almost normal to 101° or 102° and even higher. The pulse also varies, but is usually accelerated. The children or infants may or may not put their fingers to their ears or bury their heads in the pillows. Many times with no rise of temperature, and only perhaps a slight restlessness, a sudden appearance of discharge will denote a preexisting otitis.

The catarrhal form presents the same symptoms as the purulent, but of a much milder type. Adults and older children complain of pain on opening the mouth, deglutition, coughing, or any movement of the auricle; throbbing, tinnitus, fullness in the ears, with perhaps fever and delirium.

When the mastoid becomes involved unless primarily, the discharge from the middle ear lessens, there is a swelling of the superior posterior canal wall with tenderness which varies over the antrum, tip, and other parts of the bone. If a perforation of the cortex takes place there is fluctuation behind the ear. In infants the pus may escape through the Rivinian segment, make its way along the superior wall of the canal and cause projection of the auricle. There may also be a swelling of the posterior auricular glands, or one along the course of the sternocleidomastoid muscle.

When the cerebrum or cerebellum is affected, there are pain in the head, drowsiness or violent delirium, disordered speech, convulsions, optic neuritis, vomiting, constipation, and paresis of various kinds.

Sinus involvement presents the symptoms of pyæmia.

Labyrinthian complications with or without effect on drum membrane, cause high fever, intense vertigo, more or less pain, nausea, troublesome tinnitus, and impaired or lost hearing on one or both sides. Frequently this is the cause of deaf mutism.

Treatment.—For the swelling, itching, etc., of the external ear, usually a mild dusting powder, as starch, talcum, or magnesium carbonate either alone or in combination, suffices.

In middle ear disease pain is best treated with hot water irrigations using from a pint to a quart in a douche jar or bag about one foot over the head, the stream being directed to the sides of the canal. A hot water bag applied to the ear also aids. A hypodermic injection of morphine sometimes shortens an attack. Local abstraction of blood with an artificial or natural leech over the tragus may control

the trouble. Watery solutions of cocaine, atropine, or tincture of opium dropped into the canal occasionally give relief.

Oil should never be used. Saturating cotton with chloroform and blowing the vapor into the meatus sometimes acts nicely. The nose and throat should be swabbed or irrigated and kept clear of mucus. The bowels should be moved freely. A gentle inflation will sometimes dispel a plug of mucus from the origin of the Eustachian tube, and allow drainage. I have seen relief at times with one of the coal tar analgesics, dose according to the age. A 10 to 12 per cent. solution of carbolic acid in glycerin soaked in a piece of gauze and applied directly to drum membrane, by its exosmotic action, has frequently given very satisfactory results. It can be changed every six to twenty-four hours as indicated.

If the attack is not aborted and pain does not stop, the drum membrane will show signs of active congestion and even bulging. This should not be allowed to rupture spontaneously as the perforation is jagged, does not heal well, and always causes loss of audition. Paracentesis should be performed immediately. There should be no delay. The pain will be relieved, the prognosis is more favorable as the drum hears better, and what is most important the system is relieved of infectious material as soon as possible. For adults and older children I use general anesthesia with ethyl chloride or nitrous oxide while operating. Infants can be held without much difficulty. With local anesthetics I have had no satisfactory results. Cocaine is not absorbed. Anilin oil and cocaine have given toxic symptoms. Equal parts of menthol, carbolic acid, and alcohol have only been occasionally successful.

To operate, the canal should be thoroughly cleansed with a solution of 1-4000 bichloride or mopped out with peroxide of hydrogen. Then with good illumination, the knife should pass through the bulging portion or from the point at the center of the posterior section to the lower border of the membrane close to its bony attachment by a curved incision, that is, through the posterior inferior segment. At the same time I incise the mucous membrane of the internal tympanic wall and the posterior superior canal for one-fourth of an inch, down to the bone, securing thorough depletion.

If the membrane has ruptured spontaneously one should always examine to see if there is sufficient drainage; if not, a free incision should be made, including the perforation in its path. I prefer a straight knife, but one at an angle can be used. The instrument should be exceedingly sharp so as to pass through the membrane by its own weight. After the operation I irrigate with bichloride 1-5000, pack the canal lightly with sterile gauze, put a pad of cotton over the ear, and retain the whole with a bandage, which I usually leave undisturbed for 24 hours, directing the patient to lie on the side affected to facilitate drainage. When the dressing is removed I order irrigation in accordance with amount of discharge. Some cases heal in a few days.

The discharge which is at first serous, later often becomes purulent and profuse. The cleansing may be needed every two or three hours. Sterile water, decinormal salt solution, saturated solution of boric acid, or a solution of 1-5000 or 1-10000 bichloride can be used. Cotton used in the external canal should be changed frequently. These cases can also be treated by the dry method, when they can be closely watched. The ear is cleaned, dried, and strips of gauze introduced daily for drainage. In the majority of cases thus treated excellent results have been obtained.

Still a third method is to syringe the ear, use hydrogen peroxide, and syringe again. The ear is then mopped out and dried, and this is followed by repeated instillations of alcohol, diluted if painful in its full strength. I strongly oppose the use of peroxide of hydrogen, as I have seen one, and I am almost sure two, cases of mastoid involvement due to its use.

The use of powders as boracic acid, iodoform, etc., is excellent when discharge is slight and for irritation in the canal. Care must be taken not to block up the opening in the drum membrane. The powder may remain until moistened by the discharge.

Towards the end of the acute stage, inflation with the Politzer bag or Eustachian catheter helps to get rid of pus and prevents adhesions.

If the discharge continues and a chronic condition remains the ear must be kept clean. Various astringents can be used, granulations should be cauterized, and polypi removed. If there is much exposed bone, an offensive discharge, and polypi, the safest course is a radical operation. Many a facial paralysis and dural abscess with brain involvement would be avoided by an early adoption of this procedure.

If the mastoid is involved, I apply an ice bag or the Leiter coil for twenty-four hours with rest in bed, light diet, cathartics, and frequent irrigation of the canal. There must be a free opening in the tympanic membrane. If pain ceases, I stop the cold for twelve hours and when necessary reapply it for the same length of time. If the symptoms still continue I urge operation. I give no opiates to disguise symptoms, nor employ leeching or iodine over the mastoid as it prevents proper examination for tenderness.

In closing my paper, I wish to emphasize: 1. The necessity of paying attention to the removal of hypertrophied tonsils, adenoid vegetations, and nasal obstructions in all of our little patients, so that when subjected to the strain of scarlet fever they may avoid the principal method of ear infection. 2. Owing to the rapidity with which destruction of aural tissue and extension of infection take place in this disease, as soon as the tympanum shows signs of exudation and the membrane of bulging, a paracentesis should be immediately performed. 3. Repeated examinations of the ear, especially in infants and children, should be made on account of the uncertainty of the symptons.

The Suture of Perineal Lacerations.—H. Rose places the necessary sutures immediately after the birth of the child before the expulsion of the placenta. Only the first half of a surgical knot is tied and the ends of the threads are fastened to the buttock with a piece of adhesive plaster. After the completion of the third stage the sutures are tightened and the second knot tied. The author claims for the method the advantage of prompt closure of the wound, thus lessening danger of infection and greater ease of orientation in the tissues before they have had time to retract, and avoidance of increase in the tear caused by the passage of the placenta.—*Zentralblatt für Gynäkologie.*

THE EPILEPTIC CRIMINAL; WITH REPORT OF TWO CASES.

By T. H. EVANS, M.D.,
PHILADELPHIA.

It is not necessary to call to mind how much influence medicine has exerted in the modern treatment of criminals. We know the jurist has us to thank for his understanding of dipsomania, pyromania, homicidal mania, erotomania, kleptomania, hysterical assaults, and the "temporary instanity" so often mentioned in connection with suicide. That some abuse of these terms may exist, I cannot deny. But the recognition of the nature of *fixed ideas* and "uncontrollable impulses" has been an immense step forward in the interests of humanity.

The next step is the recognition of borderland states in which the patient commits crime under abnormal stress, yet with all the appearance of sanity. It is conceivable that a man may know he does a criminal act, and yet so strong may physical influence be upon him that his will cannot determine his course with the freedom and responsibility of the average individual.

This condition occurs in epilepsy; it is not constant in all cases, but approached by the majority. The reaction of the hypertonic cells is swifter and less in accord with considerate impulse, while in or near epileptic seizures the reflective consciousness of the individual recedes to the vanishing point.

When we admit the physical dangers of contagious disease, it is remarkable that at this late day so few voices urge the need of restraint of such irresponsibles as epileptics. The infinite gradations of this morbid process allow room for all the borderland states imaginable; here is the seed of major convulsions, or psychic outbursts, which may be harmful not only to the patient himself, but to innocent members of the community. These, it would seem just, should have grounds for civil suit when injured in person or property by epileptics or, indeed, any other irresponsibles. In my judgment, the suit should lie as much against the community as the particular, but irresponsible (though criminal) agent.

Case I.—L. E. St. H. G., aged 24, Latin-American. Married March, 1904. Committed a homicide two weeks after. Convicted May, 1904. Sentenced to be hanged (sentence not yet carried out). The patient has been a sufferer from grand and petit mal, with psychic equivalents, ever since youth.

At the age of 8 he ran away from his parents in Kingston, Jamaica, W. I., to join a ship. Since then his life has been largely on the sea, although he has occupied positions of some confidence and trust during the last four years in Philadelphia and other cities. On two occasions within the last seven years attacks of grand mal have occurred. The first, on shipboard, was in New York Harbor, when he fell some distance to the deck of the ship. He was sick for several months afterward as the result of head injuries received. In September, 1899, while in Philadelphia, he was attacked with what was thought to be sunstroke; this was in front of his lodging house. The symptoms as he describes them do not indicate sunstroke. The day after, although feeling confused to some extent, he was able to go to the ship for which he had signed. He has always been of an irritable temperament, and when excited, although of a timid disposition in general matters, may even be provoked into a blind and fighting rage. He bears yet scars as evidence of wounds received in accidents or physical encounters in this connection.

The patient is an undersized man, with numerous though not strongly pronounced stigmata of degeneration. The face is narrow and rather elongated, dolichocephalic, ears protruding, rather scanty growth of hair, the eyes are close-set, the nose slender and delicate, mandible slight, but not prognathous. The skeletal development is delicate; the shoulders narrow. There is some scoliosis. The eyes are anisometropic and astigmatic. The man has been of a studious temperament, with all his lack of education. He is well read, and has read more or less constantly ever since he picked up by his own efforts the rudiments of general knowledge. He has a furtive, nervous glance, and the brow furrow so often associated with cases of astigmatism and anisometropia.

Four years ago he received employment as doorkeeper in a prominent club. He also assisted in the work generally, being accorded considerable trust. In his spare time, while so employed, he would read the newspapers and magazines at hand, and suffered very much from headache. During this time, as his physician, I treated him for nervousness, acute attacks of coryza, and gastrointestinal disorders, to all of which he was continually subject. Two years ago, with the symptoms of eye-strain in my mind, and before me, I had his eyes refracted. This was done at a hospital eye dispensary. The lenses gave him no comfort, and the eye-strain symptoms did not vary.[1]

His nervousness increased. While he has no negro blood in him, so far as I can trace his parentage and family for three generations, he has a dark complexion, and some signs of mixed blood. His approaching marriage with a young girl was bitterly opposed both by her parents and his associates on the ground that he was a "nigger." This aroused him to a condition of intense excitement. About a year ago, for some irregularities in his work, he was discharged twice, but in each instance taken on again after a week or so. To some friends he began to talk in an expansive manner, intimating that he was essential to the carrying on of the place. He also intimated that members of the club would offer him frequently the use of their rain coats and umbrellas, and that his parents were very wealthy, having the ownership of immense sugar refineries in the West Indies. These states of mind would vary with attacks of depression, in which he would say that life was "not worth living, for all you could do, anyway." During this time his memory, never of the best, weakened. His condition at this time I have learned since by conversation with him and his associates, then having been personally in Europe. In the fall, with his temporary separation from his wife to be, his condition improved. Indeed, so veiled were these psychic equivalents, and so remote from our minds was the possibility of his being an epileptic—for it was not until his crime was committed that we were able to look into his case—not till then did we communicate with his former physicians in Jamaica and learn his past and definite epileptic history.

His father committed suicide at the age of 40. Two cousins have been confined in lunatic asylums. His father and two other near relatives have been subjects of alcoholism. But this information[2] from Jamaica was not received until after his conviction, which occurred within seven weeks of the crime. This is an example of the pernicious effects of what is called "railroading."

It was within three weeks of his marriage that, with the loss of work, he and his wife were, as he said, "up against it." There was no help to be expected from her parents. He went out to the club to collect some money still due him for wages. It was Sunday afternoon. In the morning he had been

nervous, absent-minded, and morose. He reached the club in the late afternoon, expecting to meet the manager, as he was told. Just what occurred we shall never know, for at that time the criminal and his victim were the only occupants of the building for the space of the scant twenty-five minutes during which everything occurred. A money drawer was opened; this constituted, technically, a mere act of larceny, not of robbery. He was met by the night watchman, with whom he had always been on good terms, though of slight acquaintance. The manager, with whom he had had several disputes, did not appear. The first encounter resulted in G. having two fingers badly bitten and receiving several staggering blows. By some means a poker was obtained and the watchman felled. Then the intruder secured from a place with which he was well acquainted, and which was in sight of where they were fighting, a hatchet. With this he showered frightful and wild blows upon the watchman. He does not remember his journey home. He says he does not remember what occurred after the first encounter.

When he reached home he had no money. He told his wife that he had been attacked on a lonely bridge. In the morning, when arrested, he claimed not to know why. Within three days two separate and conflicting confessions had been extorted from him by detectives, who put him through what is called the "third degree." The evidence as it appeared in court will sustain me in this. One detective admitted that when it seemed necessary they would use "pressure." I mention this to bring out the idea of the influence of "suggestion."

Experts at trial were not able to testify to his irresponsibility so far as their examinations during the brief time before would indicate.

It was not brought out that for three years before this, on account of intense and prostrating headaches, the patient had been in the habit of taking from three to five patent headache powders, daily. The depressive effect of bromide taken in long-continued, steady dosage, is to be remembered. Bromides do not cure headache, nor do they cure epilepsy. Psychic equivalents are very obstinate to all treatment, and are likely to appear in patients subject to grand mal under the influence of bromide.

In prison, since his conviction, it has been impossible to exercise any observation on the prisoner to determine his exact mental state. Even in well-regulated asylums many attacks escape observation.

The man shows many other epileptic stigmata. He is rapid and impulsive in speech, intensely emotional, and shows not only now, but in his past history, symptoms of sexual degeneracy. He complains of headache yet. He says his parents appear to him in his cell, and look worried. He has other sensory disturbances, and psychic irregularities.

Should such a man be held responsible to the limit of the law, for criminal acts which he may have done?

Case II.—Miss X. Y., aged about 28, in the summer of 1903, attempted to kill her lover in an excess of jealousy. He was stabbed directly in the heart, and she was held for the result of his injuries. As it happened, skillful and unusual surgery—stitching of the myocardium—saved the man's life. If the skill of the surgeon had not achieved this favorable outcome, her life most certainly would have paid the forfeit. The question arises, hereafter if any surgeon in a like case should fail to accomplish as successful results, on whom should fall the blame of the victim's death? Murder is exactly a matter of moral intention. The law constructs it as a formula. All of which should show the futility and injustice of punishment. We, of course, may advocate restraint.

In this case the woman appears to be of a borderland epileptic type, and of tainted parentage. The existence of these borderland states of epilepsy should warn us of the difficulty of determining just where punishment may be due, if we continue to insist on punishment at all. With the recovery of her victim, and his forgiveness, I believe a marriage has taken place.

Having these and other cases in mind we should arrive at conclusions, among which the following:

1. The essence of crime is in the intention, and the ability not so to intend.

2. No punishment is adequate to any crime; restraint not only after a crime has been committed, but effort to hinder any such deed, is preferable always.

3. The victims of epileptics ought to have legal ground for suit against the community as well as those in charge of the epileptic.

4. Reservations ought to be established, in which degenerates and the morally irresponsible could be colonized and treated, allowing all possible freedom of initiative for useful and safe pursuits therein.

5. Marriage of neurotics should be regulated. We can afford to lose the few sane descendants if we could also cut out their degenerate progeny. Democratic principles encourage, in this as in other matters, the average, and discourage the exceptional or abnormal—great or small.

6. All epileptics are to be viewed with suspicion. Many cases of psychic erraticism, cranks, and mistaken reformers, are to be taken as examples of epileptic psychic equivalents. The major forms of epilepsy may not prove so dangerous to the community as these veiled manifestations.

HIGHER EDUCATION A CAUSE OF PHYSICAL DECAY IN WOMEN.*

By F. W. VAN DYKE, M.D.,
GRANT'S PASS, OREGON.

The causes of physical decay in women are numerous and varied, and in the few moments that are allowed me, I can only touch disconnectedly on this one, but most important aspect of the case.

Education, in itself a most necessary thing, has been enlarged and developed, so that among the daughters of the rich and well-to-do, and to a certain extent among the poor, no girl is considered cultured unless she has broken her health down trying to learn music, Sanscrit roots, Browning and Emerson at some fashionable female college. Girls are taken at a tender age, put into elementary schools, rushed through the high schools, academies, and colleges without the slightest regard to health or capacity, too frequently for their well-being. At a time when they should be in the open air playing, or at least studying within their limits, they are forced to the utmost effort that they are capable of, for unfortunately the curricula of all schools, colleges, and universities, are no longer constructed to fit the average pupil, but the talented, and as the majority of scholars belong to the first class, the strain must be intense almost to the breaking point. Of what earthly use to the ordinary woman is a smattering

*Presidential address before the Oregon State Medical Society.

of Latin, Greek, the higher mathematics, music, and all such branches of learning? If a woman is to be a teacher, or is very talented, well and good, for there is no difference between a smart man and a smart woman; both should be learned and use their talents for their fellows' good. But nature has ordained that the vast majority of women shall become wives and mothers, and if they are exhausted mentally as well as physically, how is it possible to keep the race strong and healthy?

The craze to have every girl taught to strum on the piano regardless of talent is alone a prolific source of ill-health. Think of the money, force, and nerve power that are squandered every year on this one branch alone, and not one pupil out of five hundred can play "Hiawatha" with a correct musical interpretation. Louis Blumenberg, the 'cello soloist, said in a recent article in the *New York Musical Courier,* that in that city alone there are 25,000 piano students, and aside from the well-known professionals, not twelve of them could play Beethoven, Mozart, Chopin, or Wagner, and hardly one of this vast number could play anything at sight. If, then, there is this great waste of health and force, to say nothing of money, in the effort to teach music to girls with no talent, how must it be in colleges, where young women sacrifice their time and vitality on such problems as the whenceness of the which, psychology, and other speculative studies of no use to any one whatever, while all those things that should fit them to become wives and mothers, robust and healthy as the typical Roman matron, are sadly neglected. Every physician knows that the cramming process, in the vast majority of cases, when applied to mediocrity, is the most frequent cause of hysteria, neurasthenia, dyspepsia, astigmatism, and dysmenorrhea. Still year after year, this thing goes on like an endless curse, with constantly increasing physical disability to the women of the country. Of all these products of the higher education, or culture, call it what you will, about one half marry and produce an average of a child and one-quarter each, showing how merciless nature is in her effort to eliminate the unworthy. When these women marry, are they physically qualified to become wives and helpmeets for their husbands? That great passion which moves the world, which we call love, exists not for the majority of them. Love, aside from the bonds of consanguinity, is founded on sexuality, and a normal healthy sexuality is based on physical health. The duties of marriage rest with crushing weight on these women, and the union of the sexes, which should be as pleasurable and satisfying to the female as to the male, is practically unknown. Nature made no mistake when she originally gave desire to woman as well as to man, for it was intended to recompense her in some measure for the trials of pregnancy, and to sustain her in her hour of pain. The most perfect life, in the married state, rests on the sex element being well developed in the woman, and just as the spermatozoon, when it comes in contact with ovum, melts and fuses with it to form a perfect whole, so with man and woman, when she is normal sexually, the ideal conditions result which produces harmony, faithfulness, and unity. Then, indeed, do husband and wife become one, and no temptation can ever break the ties of love. In these happy instances divorce never takes place, and marital infidelity on the part of the man is almost unknown. Without this amativeness in the female, marriage sooner or later becomes loveless with all its attending train of evils. Wives lose affection for their husbands, and cleave to their children where no love ardor exists. Confinement in school and hard study kill desire in the woman, and also take away the physical beauty so attractive to man, and then intercourse, which should be the very apotheosis of love, becomes disgusting or is submitted to only as a painful duty, too often accompanied by further ill-health. If it be true that the literature of a nation reflects the characteristics of the people, what sexually perfect women there were in the days when the *Decameron* and *Heptameron* were written! Tannhäuser, the minstrel knight, after leaving the Venusberg, where he had lived with the Goddess of Love for a year, meets his former companions at a tournament of song, the subject of which is "Love." Tannhäuser, in an ecstacy of joy, and forgetful of his surroundings, when his turn came broke into the following impassioned lay to Venus: "Wer dich mit Gluth in seine Arme geschlossen, was Liebe ist, kennt er nur allein"; "He who with passion hath once embraced thee, can speak of love, none else its joys can prove." And why this burning tribute to Venus, which came so near costing Tannhäuser his life? Simply because she symbolized that which has ever been held precious in women, viz., beauty, grace, and that type of love which can endure much and suffer long. Imagine if you can a novelist writing in this vein: "She was pale, thin, and plain looking, with a peevish temper caused by ill-health, but Armand loved her devotedly, passionately, although lacking youth, beauty, and of a cold nature, for great was her knowledge of Theosophy, the lore of the ancients, and differential and integral calculus." Why, even Marie Corelli or Mary Johnson would not think of a man falling in love with such a heroine. Venus knew not Plato, Socrates, Browning, or Emerson, but she had the qualities that enslaved men and held them with chains of gold. The modern University graduate might know all those things that the Goddess of Love knew not, she might command respect for her intellectual gifts, but her ability to confer happiness and raise strong vigorous offspring is very limited. Pregnancy is dreaded as a calamity. Nausea, vomiting, swelling of veins, albuminuria, and other complaints more or less incidental to the pregnant state are seldom found wanting with these poor creatures. Many miscarry from sheer weakness, and only regain their usual health and strength after a prolonged period of invalidism. Without going further into this branch of the subject, how does it fare with these women in their hour of greatest suffering? If every physician in this room were asked, What are the two great difficulties encountered in so many confinements? it is safe to say the answer would be, "uterine inertia, and a slight disproportion between the fetal head and the pelvic diameters of the mother." This would be a correct answer, for a sedentary life, with hard study and lack of sufficient outdoor exercise, weakens the body and arrests the natural development of the pelvis, while the same causes enlarge the fetal head because of the increased size of the child's brain. If pains are strong enough, labor is aggravatingly slow, and the attending doctor too often puts on the forceps and the usual results follow, namely, tears and lacerations, and indeed, often enough when the labor is natural, the patient, in the common parlance of the laity, has to be "sewed up," and even then she frequently is more or less of an invalid for life. Are the diameters of the fetal head and the maternal pelvis normal, in very many instances obstinate inertia complicates the case, and that which nature intended should be a physiological process, through our artificial civilization, coupled with a contempt for nature's laws, has well nigh become pathological.

Of the children born by these women, the lack of time forbids me to go into detail; every physician

knows their shortcomings and limitations better than I can describe them. It is not to be assumed from this paper that the sole object of a woman's life is to marry and raise children, nor should she be brought up in ignorance. A woman with talent or genius should have it developed to the fullest extent, but the constant effort being made to make ordinary ability keep pace with well defined talent, is predestined to failure, because of the inexorable laws governing our being. The draught horse can not turn the race track with the fleet trotter, but he is none the less valuable for that; on the other hand, the world could dispense with the racer, but the faithful, honest beast of toil is a necessity. How is this state of affairs to be changed? It cannot be done in a day or a year, but as it was a thing of slow growth, so by degrees we must return to health and happiness. Revise the studies of schools and colleges to suit the majority, and let no girl be forced to go beyond her capacity to learn with a moderate amount of application. Cease torturing girls with the piano when they have no talent, for if they have a love of music in their hearts, they will work at it with pleasure for art's sake alone. Music is a most jealous mistress and demands much talent and labor before she will yield herself. One of the greatest fallacies of the times is the idea that a person to be interesting must be educated, when the truth is, that if uninteresting while uneducated, mere polish will not make one attractive.

Hercules in his struggle with Antæus discovered that when his antagonist touched mother earth, he gained strength, and could only be crushed by holding him from the ground. Is not this emblematic of the deterioration and ultimate decay that await those who shut themselves up with books, and close their eyes to the great open page of nature? Penelope the faithful wife, Cornelia the proud mother, whose children were her jewels, Thusnelda, the ideal of the ancient Germans, and St. Elizabeth the personification of Christian faith and charity, knew nothing of soul yearnings, telepathy, psychology, and other useless things, but they possessed those womanly qualities which have sent their names down the ages, and will continue to do so, until the name of the last graduate of the woman's college shall have faded from the recollection of men forever.

Resection of the Stomach.—Rydygier describes a new operation in two stages intended for the removal of large pyloric growths. The steps are as follows: First operation—The usual median incision; section through the stomach on the cardial side of the tumor after the application of clamps; cutting the jejunum across 30-40 cm. below the duodeno-jejunal fold; insertion of the proximal stump into the side of the distal one, at a point 15 cm. below the line of section and insertion of the free end of the jejunum into the lower end of the gastric wound, which is closed up to this point. Then a stomach tube is passed through the pylorus well into the duodenum, and the pyloric stump sutured into the skin incision, which is closed up to the point of emergence of the tube. Second operation—The wound is reopened and the pylorus with adjoining structures, and, if need be, part of the duodenum, is removed, and the duodenal stump closed and dropped back. Permanent suture of abdominal incision. The method offers the following advantages; it is less dangerous, since it is in two sessions, and the patient can immediately be given forced feeding through the stomach tube. No food comes in contact with the newly sutured stomach. The patient is forced to submit to a second operation, which is often refused if a simple gastroenterostomy be done at the first sitting. The conditions are most favorable for complete extirpation of the growth.—*Zentralblatt für Chirurgie.*

The Medical Aspects of Acute Appendicitis.—Andrew MacFarland declares that the surgeon is apt to base his statements upon the severe forms of appendicitis which he meets, and does not include in his view the vast majority of cases which run a mild course, do not need operation, and recover perfectly. The object of the physician should be to ascertain the method of treatment which in general gives the best results for the class of cases which come under his care, and to modify such treatment in any individual case as the condition warrants. Under any circumstance, there will be some mortality rate, whether the treatment be medical or surgical. The writer gives statistics from various sources which are in favor of medical treatment. Personally, he has never had a case of acute appendicitis die, nor has one been operated upon in the acute stage. General statistics contradict the statement that appendicitis has become far more frequent and virulent. The apparent increase is due to an improvement in diagnosis. Cases of acute appendicitis recover without operation in from 90 per cent. to 95 per cent. of cases, and relapses occur in not more than one-fourth of the cases. This is the mortality rate under every imaginable medical condition, favorable or otherwise, while Deaver and Richardson have a mortality rate of 5 per cent.—these cases having the best of surgical care. The importance of intestinal quiet in preventing the extension of infection cannot be overestimated. Examination of the rectum should always be made, especially in women, to distinguish the condition from pelvic inflammation. A careful differential diagnosis should always be made. From study of the blood, it would appear that if the leucocytosis count is low on the fourth day the organism evinces such a poor reactive power that it cannot possibly resist the added exhaustion of an operation. Thus it seems that in these cases non-operative procedure is necessarily preferable. Absolute rest and complete fixation should be provided. An ice bag applied locally over the appendix, withdrawal of all food except a little sweetened water, which is absorbed by the stomach, and the use of rectal suppositories of opium in moderation to stop intestinal peristalsis and to mitigate pain, seem to attain this end. The bowels are allowed to remain constipated for a week or ten days, and are then gently washed out with normal salt solution. After the subsidence of the acute condition, the question of operation, which is then practically free from mortality, can be considered.—*Albany Medical Annals.*

Total Absence of Patellæ in a Young Child.—Herman F. Senftner reports this case. The patient is the seventh of a family of eight children, all of them living and in perfect health. They are of Irish descent. There is no family history of syphilis, rheumatism, or tuberculosis. The mother states that at the fifth month of gestation, she sustained a sudden fright because of the entrance of a burglar into her apartments. During her entire pregnancy, in her daily walks she was obliged to pass a man living in the lower part of the house, who had been unable to walk since early childhood, although apparently possessing both lower limbs in normal condition. The patient is now 4 years of age, and is very active. There is no history of fall or injury. The writer presents a Röntgen ray photograph showing a total absence of both patellæ, and an absence of the centers of ossification of these bones. The child maintains her lower limbs in a position of hyperextension in order the more easily to support the center of gravity of her body. Her gait resembles the action of a first-class lever with the hip joint as a fulcrum, the thigh and leg being carried forward and backward as a single mass, and immovable, as it were, at the knee joint. The child plays ordinary games. But when it is necessary in any way to flex the knee joint, as in walking upstairs, she is absolutely unable to accomplish the feat.—*Archives of Pediatrics.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, February 25, 1905.

THE TREATMENT OF PNEUMONIA.

DR. BEVERLEY ROBINSON has recently published in pamphlet form three articles dealing with the treatment of pneumonia, written by him within the past few years. The first of the series, the most recent as to date, appeared in the *American Journal of the Medical Sciences* for December, 1904, and treats of some unsettled and important problems in the treatment of acute lobar pneumonia. Before referring to treatment, the author says a few words in regard to prevention, calling especial attention to some facts which later investigations of others and personal observations render valuable.

He points out that it is known to-day that the pneumococcus is found in the secretions of the throat and mouth of many healthy persons, and for long periods of time. One or more of the contributive causal conditions may render these microorganisms virulent or infective. Is it not then, he asks, specially indicated to make use of antiseptic gargles and mouth-washes frequently when we have reason to fear the possible beginning of pneumonia? This antiseptic mouth-wash, at such times, should have a slightly acid reaction, simply because we know that the pneumococcus does not thrive in an acid medium.

As soon, however, as the first symptoms of chill, fever, pain in the side, cough, and expectoration set in, Dr. Robinson believes that beechwood creosote should be vaporized more or less continuously in the patient's room, as he is confident there is no drug of more preventive value in pneumonia. He doubts the reality in the majority of instances of risk of contagion through the air, although he advises that the best known methods of preventing such an occurrence should be adopted. Emphasis is laid upon the necessity of a large, well-ventilated room, with open fireplace if possible, of two well-trained, careful, judicious, and attentive nurses, of proper assimilable food (mainly milk), of a sufficient quantity of drinking water, and of due attention to the emunctories. In the treatment of acute lobar pneumonia the following propositions are emphasized by the author: 1. To begin judicious rational treatment immediately and to continue it during the attack. 2. The most useful single agent in treatment, preventive and curative, is creosote, used preferably by inhalation, and continued for a sufficient length of time. 3. Strict avoidance of extremes of treatment in any direction, whether it be toward the use of so-called specifics or the employment of certain drugs, notably digitalis and strychnine. 4. It should be graven on our minds that pneumonia may be throttled or minimized most surely in the beginning. Later, when the disease is fully developed, our rôle is inferior, but should consist mainly in doing least harm. 5. Harm is done almost invariably by ignorance or undue enthusiasm.

The second paper of the series is upon the treatment of croupous pneumonia, and is reprinted from the "Transactions of the Association of American Physicians," 1894, vol. ix. In the first stage of croupous pneumonia, the two symptoms which are of special interest as regards the efficacy of treatment are pyrexia and pulmonary congestion. Dr. Robinson has not thought it wise, as a rule, to give the modern antipyretic drugs except in occasional doses. He believes that quinine in doses of 3 to 5 grains every four to six hours is on the whole the most efficacious remedy both to reduce temperature and for its beneficial effects upon the circulation. Of cool baths, cold sponging, etc., as these are usually employed, he has not the high opinion which is professed by so many practitioners. Neither does aconite in the treatment of pneumonia find much favor with him, as he dreads its pernicious action on the heart. The author confesses himself a strong believer in the value of small repeated doses of antimony in the pulmonary congestion and pyrexia of croupous pneumonia. Nitroglycerin, given by the mouth or hypodermically is another drug strongly to be recommended whenever the heart is particularly taxed by reason of the pulmonary congestion and a tendency to edema. The drinking of copious draughts of water is a point especially dwelt upon, a far wiser procedure in the treatment of pneumonia, according to Dr. Robinson, than forcing patients to take milk, beef tea, or broths of different kinds. As to the use of alcohol in this disease, the question is one in which views differ widely. Dr. Robinson avers that in nearly every instance its judicious use should be advised. But he states that the following conditions are absolutely contraindications: 1. Cases in which the patient is already highly plethoric and in which the mass of blood, rich apparently in all nutritive qualities, would merely have this state exaggerated, as it were, by alcohol, which is so readily and rapidly assimilated and thus becomes positively a hindrance to the vital functions. 2. Cases in which the hepatic engorgement and gastric catarrh render the use of alcohol inadvisable because nausea and gastric intolerance are increased by its exhibition even in moderate amount, and thus assimilation of food and water is prevented. For the relief of the heart failure or pulmonary hyperemia—the two dangers most to be feared in the stage of hepatization as well as at the time of the crisis—Dr. Robinson believes in the employment of strychnine in large doses. He is entirely opposed to the use of digitalis, or digitalin, except in very small doses, and then only to control cardiac irregularity when it occurs. Repeated doses of strong black coffee and alcohol (when not specifically contraindicated) are praised emphatically, but the spirit, brandy or rum, should be old. Coffee or alcohol will be assimilated and hold the vitality of the patient when other food or stimulant will be of little or of no apparent benefit.

The last paper of the series bears the title of "Suggestions as to Prophylaxis, Contagion, and Treatment of Pnemonia," and was first published in the MEDICAL RECORD for February 19, 1898. With regard

to the contagiousness of pneumonia, Dr. Robinson, guided solely by his own observations, regards this risk as relatively small, although the testimony of numerous competent observers would seem to prove the contagious character of the disease. The author mentions one matter of much interest in connection with pneumonia, namely, the possibility that one may take pneumonia in part and not necessarily the whole disease. "More than once," he says, "I have noticed that when visiting a hospital ward where pneumonia cases were numerous I have suffered from headache and general malaise. These symptoms I have attributed, when no other sufficient cause was evident, to breathing too much of the poisonous or infective exhalations. Not only my own impression exists that certain symptoms are produced by inhaling either pneumonia, diphtheria, or other poison-laden atmosphere, but the observations of other clinicians corroborate this view. Alongside of numerous morbid manifestations in the localization of the pneumococcus upon different viscera, there exist pathological affections attributable to the same microorganism and in which there is no appreciable organic determination. These are the incomplete, rudimentary forms of the pneumococcus infection."

Prophylactic treatment of pneumonia is based mainly upon its probable origin as a germ disease, and the author recommends washing a catarrhal nose or throat with an antiseptic—such as boric acid solution—in time of epidemic.

DENTITION AS A FACTOR IN THE ETIOLOGY OF EPILEPSY.

Epilepsy must be considered a disorder in which the stability of the neuromotor mechanism especially is deranged in consequence of a variety of influences. It would appear that the primary essential of this condition is a state of heightened susceptibility—congenital or acquired—on the part of the nervous system, and that this may be acted upon by a number of different agencies. Such a view would help to explain the part played by the process of dentition in the etiology of the convulsions of childhood, which only too often are the precursors, if not the actual beginnings of true epilepsy. Under these circumstances dentition acts as the exciting cause, the susceptibility constituting the predisposing influence. Given the latter, the former becomes capable of operating; while if the susceptibility is wanting, the process of teething, no matter how difficult, is incapable of evoking the convulsive seizure. Further, the attack ocurring in infancy or childhood may or may not be repeated later in life in accordance with the degree of susceptibility and the intensity of the exciting factor.

Some interesting data bearing upon the discussion in hand are presented by Dr. W. P. Spratling, in an article in the *Medical News,* December 10, 1904, who observed among the cases of epilepsy admitted to the Craig Colony the strikingly large proportion in which the attacks began during the first year of life, especially at the seventh month, covering the period of the first dentition, and during the sixth, seventh, and eighth years, covering the period of the second dentition. A correspondingly large number of cases had their inception between the twelfth and sixteenth years, that is, at the period of puberty. In accordance with the facts, therefore, the conclusion seems justified that difficult dentition, the piercing of the gums by the teeth, may in predisposed subjects, constitute a sufficient irritant to excite convulsions, and these may ultimately lead to true epilepsy. Those infants may be considered as predisposed who inherit a neuropathic tendency, whose parents were epileptic, insane, or alcoholic, or suffered from some other general vice that could be transmitted to the offspring in a form capable of vitiating its powers of resistance to disease. It seems unlikely that difficult dentition alone is capable of causing epilepsy in a child free from such ancestral taint and free at birth from a tendency to nervous disease. The same result may be brought about by other sources of irritation, such as gastrointestinal disorders, the eruptive fevers, and the like.

The Contagiousness of Leprosy.

According to a despatch in the newspapers said to originate from one of the consulting physicians to the Louisiana State Leprosy Camp, there are two hundred lepers walking about the streets of New York city, who constitute a constant menace to the population. This assertion has been met by the reassuring statement from one of the Board of Health physicians, who is in a position to know the facts, to the effect that there are only three cases of leprosy in the city known to the Board of Health that are not being cared for in institutions, and that it is very unlikely that there are many others. A firm belief in the contagiousness of leprosy is a popular conviction that seems almost ineradicable, perhaps owing to Biblical associations, yet most authorities now claim that the disease is only mildly contagious, if so at all. In this connection it is interesting to note the résumé of Dr. Zambaco's views given in our letter from Constantinople in another column. Dr. Zambaco, who has made the consideration of this question his lifework, and who for thirty-two years has given himself to the study of lepers in their natural surroundings, has never met with a single case of contagion, and believes that, in spite of the isolation of the bacillus of leprosy, other factors, notably those of heredity, play the dominating rôle in the transmission of the disease. The committee appointed by the New York Medical Society in 1896 to investigate leprosy also came to the conclusion that the malady, though infectious, is not necessarily contagious, and that factors other than mere proximity are necessary for its conveyance. On the other hand, the contagionists, as represented by the Berlin Conference of 1897, still maintain the extreme virulence of the contagium of leprosy and deem it equal to that of smallpox and plague.

Is Consumption Curable?

This question has been asked and answered in a more or less satisfactory manner many times during the past few years. The general conclusion reached has been that if rational treatment is instituted and conducted for a sufficient length of time, in the early stage of the disease, consumption is a curable disease; but that, if the disease has been allowed to proceed to great lengths, the chances are greatly against ultimate recovery. Even in advanced cases, however, life may be greatly prolonged if treatment be conducted upon the most approved modern system, fresh air and sunshine *ad libitum* and suitable diet. In a paper on the subject read before the Ohio Valley Medical Association, at Evansville, Ind., Dr.

Paul Paquin thinks that the apathy with which the world regards consumption is due to the following causes: 1. Because the majority of the medical profession continues to consider tuberculosis, particularly pulmonary tuberculosis, as incurable in any event. 2. Because this circumstance and the lack of instruction in sanitary science in our system of education have produced a public mental attitude of wanton optimism. 3. Because there remain here and there a few who reject facts of infection mathematically demonstrated the world over and continue a public crusade in favor of their mistaken ideas. 4. Because when tuberculosis is recognized the truth is often concealed so long from the patient and relatives that the former loses precious chances of recovery and is allowed to disseminate the disease broadcast. 5. Because, by the marriage of consumptives, prolific new centers of infection with far-reaching fatal influences reinforce the popular idea of unavoidable pathogenic perpetuity. 6. Because, the diagnosis of the disease, in the great majority of cases, is made too late for any measure of prevention or cure to be effective. Dr. Paquin thinks that medical students and post-graduate students should be more carefully instructed as to the diagnosis of the symptoms of incipient pulmonary tuberculosis. If the pathology and clinical factors of the borderland of the disease were better known by many medical men, he is of the opinion that consumption in its early stage would be more frequently diagnosed. There can be no doubt that the crux of the problem is in early diagnosis, and of course it would be to the best interests of everybody for the physician to be a skilful diagnostician. But perhaps the most common cause of consumption being allowed to go too far, is that the sufferer himself, either through ignorance or for pecuniary reasons, does not consult a physician until too late.

Liquor Drinking in Europe and in the United States.

In the *Sun* of February 5 was a despatch from London, giving certain facts from an English official return as to the consumption of alcoholic beverages by various nations during the year 1903. According to this report, at that time the Bavarians were the greatest beer drinkers, averaging 51 gallons a year each, but of the nations Belgium came first, with an average consumption of 47.7 gallons. The United Kingdom averaged 29.7 gallons, and America was sixth on the list, with an average consumption of 15 gallons. With regard to the consumption of wine, France led with 30.2 gallons, while America was last on the list with 0.4 gallons. Denmark was the largest consumer of spirits per capita, averaging 3 gallons for each member of its population. The United Kingdom consumed .99 gallons per head. The consumption in the United States was not given, but is stated to have been greater than in the United Kingdom. The report stated that so far as the revenue derived from alcoholic beverages was concerned, the United Kingdom had the highest proportion, 32 per cent. The United States came next with 29 per cent. Several other countries had 19 and 18 per cent., and the average was 8½ per cent. Drinking throughout the Continent of Europe is probably on the increase, in France and Belgium the habit shows no sign of decrease. Beer drinking in Germany is still one of the features of national life. In Great Britain the temperance movement has during the past few years made great strides, and the drink bill of that country decreases steadily year by year. There has been a strong stand made by the Government and prominent persons against excessive drinking in the United Kingdom, and the benefits of the movement are beginning to be shown. Drinking in the United States, although less than in Europe, has increased within the past few years. Probably the statement made recently by Dr. Wiley that something like 85 per cent. of the whiskey sold over the bar in America is adulterated, combined with the public exposure of the wood alcohol scandal, may deter some people from drinking that spirit.

Need of More Matrons at Police Station-Houses.

The sixtieth annual report of the Women's Prison Association and Isaac T. Hopper Home has just been issued. Included in the report of the prison visitor is a statement that there is a lack of matrons at various station-houses. In some precincts in which abandoned women abound, notably the fifteenth and eighteenth precincts, the women when arrested are not brought to the matrons, but are charged with disorderly conduct and furnish bail. The matrons in the twenty-first precinct are supposed to receive all women arrested in the eighteenth, but, according to the statement of the women themselves, those who can furnish bail are held in the eighteenth until the bondsmen arrive. At the present time, the report goes on to state, matrons are assigned to 19 precincts out of 32 in the Borough of Manhattan; to 9 precincts out of 32 in the Borough of Brooklyn; to 3 precincts out of 8 in the Borough of the Bronx; to 2 out of 9 in the Borough of Queens, and to one precinct in the Borough of Richmond. It is argued that a sufficient number of women and lost children are received in each station-house in the Borough of Manhattan to warrant the appointment of matrons thereto, and that for the sake of ordinary decency alone these appointments should be made. Undoubtedly, women of whatever description should not be left in charge of men, and at least one matron should be on hand in every station-house.

To Study Territorial Diseases.—The government of the Canadian Northwest Territories has established a bacteriological and pathological laboratory at Regina, and Dr. George Charlton has been appointed to take charge of the work. For the present the laboratory will be situated in the government building in connection with the department of agriculture. The first research to be undertaken is an investigation of the nature of a local disease of horses known as swamp fever, which is rapidly fatal and occasions considerable losses yearly to the ranches. The nature of the malady is to be determined, and then if possible means of treatment and prophylaxis are to be devised. The recent epidemics of diphtheria and typhoid fever will also be studied.

A New Cure for Seasickness.—A London dentist is said to have invented a self-leveling steamship bunk which is designed to remain in the horizontal position no matter how heavily the vessel is pitching or rolling. The cot is suspended from a steel framework by cords at each corner which are operated by electric motors in such a way as to counteract all motion of the boat, and automatically maintain the cot in a horizontal position. By pressing a button an electric fan may be made to drive a current of air across the face of the occupant. The inventor, who has spent more than three years in perfecting the device, says that, although he is one of the worst sailors who ever boarded a ship, in his swinging bunk he is now able to brave the worst weather at sea without a qualm. Two of the Channel steamers are to be fitted with the new appliance.

News of the Week.

Army Medical Corps Examinations.—Preliminary examinations for appointment of Assistant Surgeons in the Army will be held on May 1 and August 1, 1905, at points to be hereafter designated. Permission to appear for examination can be obtained upon application to the Surgeon General, U. S. Army, Washington, D. C., from whom full information concerning the examination can be procured. The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, shall be of good moral character and habits, and shall have at least one year's hospital training or its equivalent in practice. The examinations will be held concurrently throughout the country at points where boards can be convened. Due consideration will be given to the localities from which applications are received, in order to lessen the traveling expenses of applicants as much as possible. In order to perfect all necessary arrangements for the examination of May 1, applications must be complete and in possession of the Surgeon General on or before April 1, and for the examination of August 1, on or before July 1. Early attention is therefore enjoined upon all intended applicants. There are at present twenty vacancies in the Medical Corps of the Army.

The Röntgen Congress in Berlin.—The Berlin Röntgen Society has arranged for a congress in commemoration of the first decennial of Röntgen's discovery, to be held in Berlin from April 30 to May 3, 1905. The Executive Committee of the Congress and Exhibition is composed of Drs. Eberlein, Immelmann, and Cowl, who will receive and acknowledge notifications of membership, contributions to the proceedings, and other communications concerning the Congress and Exhibition. Cards of membership will be issued, from and after April 27, at the Bureau of the Congress. The cost of the same, entitling also to the volume of proceedings, is 15 marks, or 15 British shillings, or $3.60, which may be sent in advance to the treasurer, Dr. W. Cowl, Gleditschstrasse 6, Berlin. Early notice of participation, with precise address, title of paper, etc., is desirable. It may be found necessary to restrict the time devoted to the single communication, discussion or demonstration. An explicit circular concerning the Exhibition, which is to be devoted to new and interesting articles pertaining to the Röntgen ray, will be sent on early application. Speakers in English, who may send in a short digest before the Congress, will secure, as far as is possible, a rendering of their remarks in German at their close.

Appropriations for City Hospitals.—Upon the recommendation of the Committee on Finance the Board of Aldermen has authorized an issue of $144,329 of corporate stock for the purpose of increasing the size of the plot upon which the new Harlem Hospital is being built, at Lenox avenue and 136th and 137th streets. For the improvements at Bellevue Hospital $20,000 was appropriated, and $30,000 for additional street signs in the Borough of Manhattan.

Ether Explosion in a Hospital.—While a clinic of Temple Medical College students was going on at the Samaritan Hospital there was an explosion of ether. Two physicians and two students were injured and fifty others narrowly escaped harm. Drs. L. W. Cunningham and H. A. Duncan, residents at the hospital, were seriously burned about the head and arms. Daniel Kennedy and James Crawford, students, were similarly though less seriously burned. Dr. W. Wayne Babcock was directing preparations for the operation, but was not injured The flames were quickly extinguished.

Consent of Patient Must be Obtained Before the Performance of a Major Operation.—The decision of an Illinois court affirming a finding of $3,000 damages against a surgeon charged with operating upon a woman without her consent, will be taken to the Supreme Court of the State. The decision of the lower court was rendered in 1897, and that of the Appellate Court was handed down last week. After the operation, it was claimed, the plaintiff's condition became critical, and she is now a patient in the Kankakee Insane Asylum. The decision of the Appellate Court is that any surgeon who performs a major surgical operation without the consent of the patient is liable to damages. The consent of the nearest relative does not relieve the surgeon of the liability.

Smallpox in Illinois seems to be on the increase, as during the past week twenty-seven cases were sent to the Isolation Hospital in Chicago. Four had old scars said to be from vaccinations made in early childhood, but had never been revaccinated. Twenty-three never had been vaccinated at all; seven were unvaccinated children under the school age of six years. Twelve of the patients came from down-town lodging houses. Not even a telegraph message, it is said, can reach Smithfield, a village forty miles west of Peoria, Ill., so strict is the smallpox quarantine and so great is the ravage wrought by the malady. The last means of communication with the outside world was cut off when the telegraph office was closed by the illness of the operator. Many deaths have occurred and the State officials have prohibited the stopping of trains at the village.

The Oppenheimer Company.—According to the *Tribune* of this City several of those whose names have been published as indorsers of the Oppenheimer treatment of alcoholism have issued an announcement withdrawing their endorsement of the enterprise. Among those who have refused to permit the further use of their names as sponsors for the method are Bishop Potter, Rev. Dr. Parkhurst, Rev. Robert Collyer, Hon. Chauncey M. Depew, and Mr. J. D. Kennedy of this City, and Rev. Floyd W. Tomkins of Philadelphia.

Willard Hospital Dedicated.—Simultaneously with the unveiling of the statue of Frances E. Willard at Washington, February 17, the Frances E. Willard National Temperance Hospital, Chicago, was formally dedicated. Following the ceremonies a public reception was held, and many visitors inspected the hospital. The building is four stories high, built of pressed brick, and has 75 beds. The corner-stone was laid in September, 1903. The hospital was founded twenty years ago.

The Medical Library and Historical Journal.—The establishment of the printers of this journal was almost wholly destroyed by fire on February 13. The January issue of the journal was on the press and the plates were lost. Fortunately duplicate copies of all important manuscripts were made before sending them to the printer, so the heavy loss incurred by the Journal will not be shared by its contributors or readers. The editor announces that immediate steps have been taken for the making of new plates and duplicating the entire number which was in press and that this issue will be published at the earliest possible date.

New Law Relating to Morgues.—The Health Committee of the City Council of Chicago recently recommended an ordinance to compel every hospital to maintain a morgue for the care of those who die in the institution until relatives have been notified. Un-

less permission is given by the relatives, bodies cannot be removed from hospitals for twenty-four hours after death.

The Canton, Ohio, Medical Society.—The annual banquet of this society took place a short time ago and was the occasion of a notable gathering of members and invited guests. At the January meeting of the society the following officers were elected: *President,* Dr. E. J. March; *Vice-President,* Dr. G. A. Kelly; *Recording Secretary,* Dr. C. F. Schiltz; *Corresponding Secretary,* Dr. L. D. Stoner; *Treasurer,* Dr. Frank D. Hinden.

The Australasian Medical Congress.—The seventh session of the Australasian Medical Congress will be held in Adelaide, South Australia, during the week, September 4 to 9, 1905, under the presidency of Dr. E. C. Stirling. There will be seven sections, viz., Medicine; Surgery; Gynecology and Obstetrics; Eye, Ear, and Throat; Pathology, Physiology, and Pharmacology; Public Health; State Medicine and Medical Ethics.

Imperial Support of the Teetotal Movement in Germany.—German army officers are henceforth to be allowed to drink to the health of the Kaiser or anybody or anything else, in plain water instead of beer or Schaumwein. This permission was given in answer to a request by Dr. Adolph Banzer of Munich, a member of the Society Against the Misuse of Spirituous Liquors, asking whether officers might drink toasts in water. The Prussian minister of war replied that the Emperor has replied to the inquiry to the effect that "no compulsion exists to partake of toasts in alcoholic drinks, and that it may be left to the movement now in progress to advance this idea in all circles."

Dr. Joseph A. Hall of Cincinnati, a captain in the Ohio National Guard, has been appointed to the staff of Governor Herrick.

Dr. H. D. Hinckley has been elected Dean of the Cincinnati Polyclinic and Post-Graduate Medical School.

Osteopaths Not Physicians.—The Missouri Supreme Court has rendered an opinion in which it holds that osteopathists are not physicians and surgeons under the laws of that State, and that if they attempt to treat diseases they are responsible for damages resulting from injuries sustained by the persons under their care.

Banquet to Dr. Simon.—A testimonial banquet in honor of Dr. John H. Simon, Health Commissioner of St. Louis, was given on February 11, and about three hundred guests attended. Mr. William Marion Reedy acted as toastmaster. Among the speakers were Lieut.-Governor Chas. P. Johnson, Dr. W. G. Moore, Judge Jas. R. Kinealy, and James Hagerman.

Early Diagnosis of Pulmonary Tuberculosis.—The Illinois Board of Health has just issued, for distribution to the physicians of the State, a pamphlet setting forth succinctly and systematically the various signs, general and local, by which an early diagnosis of pulmonary phthisis may be made. An examination of sputum for tubercle bacilli will be made by the laboratory physicians of the Board of Health, without charge, for any Illinois physician.

The Osteopathic Bill, introduced recently into the New York Senate, has been introduced into the Assembly and referred to the Committee on Public Health. The public hearing on the measure will be on March 1, at 2 P.M., before the Senate Judiciary Committee and the Assembly Committee on Public Health, in the Judiciary Committee Room in the Capitol.

State Board of Health of Illinois to Enlarge the Scope of Its Work.—The laboratory work of this Board is to be so increased that it will become of greater benefit to the physicians of the State. Container stations will be established in every county of the State, where containers for bacteriological specimens in blank forms for transmission may be secured in the shortest possible time. It is thought that these containers will be placed in the hands of secretaries of county medical societies for distribution.

A Non-vegetarian City.—The municipal authorities of Berlin after due consideration have decided to refuse a legacy of 500,000 marks left to the city by the late Professor Baron of Bonn. The money was to be used for the purpose of founding an orphanage which should bear the donor's name, and in which children should be brought up on an exclusively vegetarian diet. An additional condition was to the effect that no medical man should be allowed to sit on the board of directors.

A Bill to Stop Incubator Exhibits.—The managers of places of amusement who exhibit infants in incubators will be guilty of a misdemeanor if a bill now before the Legislature at Albany is enacted. The measure has been introduced at the instigation of the Society for the Prevention of Cruelty to Children.

For a New Census.—Health Commissioner Darlington has applied for an appropriation to meet the expenses of taking a new census of the city. As the last Federal census is supposed to have underestimated the population of the crowded sections the death rate of the city is made to appear higher than it really is.

A Monument to Virchow.—The city of Berlin has planned to honor Rudolf Virchow's memory by the erection of a monument to be placed at the intersection of the Karl- and Luisen-Strasse, a square which will henceforth be known as Virchow-Platz.

Obituary Notes.—Dr. T. Melville Lippitt of Columbus, Ohio, died on February 10, of laryngeal stenosis, at the age of thirty-two years. He was born at Mount Vernon, Ohio, and graduated from the Starling Medical College in the class of 1897. He practised in Columbus, and was one of the rising young men of the profession at the time of his death.

Dr. Elihu Russell Houghton died at his home in this city on February 19, from appendicitis. He was born in Jersey City in 1864; was graduated in arts from Amherst in 1885, and in medicine from the Bellevue Hospital Medical College in the class of 1888. He had served in the United States Navy and in the Immigration and Marine Hospital Services.

Dr. Henry F. Hendrix died at his home in St. Louis on January 28, aged sixty-two years. He was graduated from the St. Louis Medical College in 1874, and practised in St. Louis for twenty-eight years.

Dr. John Shore, formerly one of the pioneer physicians of St. Louis, died at St. Charles, Mo., on January 30, at the age of eighty-five years. He was graduated from the Jefferson Medical College in 1842. He was born in Petersburg, Va., July 11, 1819.

Dr. James T. Renouf of Atlanta, Ga., died on February 19, of angina pectoris. He was a graduate of the Southern Medical College in the class of 1887.

Dr. Israel T. Hunt of Boston died February 16, from the results of a fall. He was sixty-five years old and was a graduate of the Harvard Medical School in the class of 1870.

Dr. H. R. Van Rensselaer of Springfield, Mass., died February 13. He was born in Saratoga County, N. Y., and was graduated from the Albany Medical College in 1882. He practised for about seventeen years in Pittsfield, but was forced by illness to retire from active work.

Correspondence.

THE NEW YORK MEDICAL GYMNASTIC AND MASSAGE SOCIETY, AND THE KINESIPATHY BILL.

To the Editor of the Medical Record:

Sir:—The New York Medical Gymnastic and Massage Society wishes to correct the impression that it has had anything to do with the bill now before the Legislature in regard to a special State licensing of practitioners of Massage or Medical Gymnastics. No one has ever been authorized to associate our Society with such a bill. Our Society has always stood opposed to any legislative measure along this line. Letters to his effect have been sent to Senators Fitzgerald and Brackett.

H. C. Thompson, M.D., Secretary.

New York, February 20, 1905.

OUR LONDON LETTER.

(From Our Special Correspondent.)

PRINCESS VICTORIA'S ILLNESS [illegible] OF GYNECOLOGY—HEMATURIA—OOPHORECTOMY FOR MAMMARY CANCER—TROPICAL EXPEDITIONS—BRITISH ASSOCIATION.

London, February 3, 1905.

A good deal of sympathy is felt for the Royal family as the Princess Victoria has undergone an operation for removal of the appendix, which had for some time given sufficient cause for considering the advisability of such a course. After a recent mild attack of influenza the symptoms became decided, and the operation was determined on. It was uncomplicated and H. R. H. is progressing most favorably.

Professor J. W. Taylor in his valedictory address as president of the Gynecological Society gave some interesting notes on recent progress. His own work was coterminous with the existence of the society which he joined at the outset, 20 years ago. In that time he had performed 1,291 operations, with only 85 deaths. Many of these deaths were not due to the operations. His best work he considered was in the latter part of the time—the last five or six years in which his mortality had fallen to 1 per cent. His experience extended over days of ignorance, when everything favored infection, days of empirical asepsis, and the later days of knowledge. He attributed the greatest importance to the recognition of heat as a sterilizer, disinfection of the hands by permanganates, spirit, and biniodide of mercury, not merely before operation, but after every dangerous contact. Also to the substitution of fine, interlocking, chain sutures of silk, instead of ligaturing *en masse*. He found fine silk was absorbed in time as completely as catgut. Pelvic hematocele, the so-called broad ligament hematoma, formerly the commonest post-operative complication, he had not found due to the use of a sharp needle as had been supposed. It was more likely due to ulcerative erosion of vessels owing to infection from the thick silk used for tying the pedicle. Removal of the appendages for myomata had been largely abandoned in favor of abdominal or vaginal hysterectomy, and he now seldom performed it for gonorrheal tubal disease, preferring treatment with biniodide of mercury. Even in cases demanding operation, this may be combined with evacuation of the sac and drainage—a plan superior to the old operation.

In inguinal celiotomy by the method of Reclus he found that by tying off a small amount of mesentery at each side of the spigot of glass, at the original operation, the subsequent division of the intestine was practically bloodless. In conservative operations some of his greatest successes had been the separation of adnexal adhesions to the intestines, causing obstruction; hysteropexy and ventrosuspension were also conservative, but he had found conservative operations on the appendages rather disappointing. In simple prolapse of the ovary from retrodisplacement he found the best plan was to shorten the round ligaments without opening the peritoneum. He had given up anterior in favor of posterior colpotomy, and said there were advantages in this procedure even in virgins and children; the essential points were thorough disinfection of the vagina, and free drainage with iodoform gauze. Increased consideration might well be given to vaginal ovariotomy and vaginal enucleation.

A paper on hematuria, by Dr. A. E. Garrod, at the Medical Society, brought out a number of interesting observations in the course of the discussion that followed it. Dr. Garrod said the chief interest in the symptom was clinical, in which it differed from hemoglobinuria. The ozonic ether and guaiacum test was very delicate, and failure to obtain the blue rings was satisfactory evidence of the absence of blood. He mentioned the possibility of renal sarcoma in infants and infantile scurvy as sometimes accounting for obscure hematuria. Hemophilia is also to be remembered as well as the more common causes, nephritis, calculus, etc. The Bilharzia and rarer causes were also considered. Instances from eating rhubarb—some in only small quantities, also occurred. Dr. Bruce Porter mentioned the case of a man of 50, who had two attacks after eating large quantities of asparagus. Dr. T. H. Kellock spoke of papillomatous growths in the kidney, and he, as well as Dr. J. H. Bryant and Mr. Swan, emphasized the value of the cystoscope. The last-named speaker instanced the case of a lad whose bladder had been opened to deal with a suspected papilloma, but nothing was found, though subsequently a tuberculous condition was discovered by the cystoscope. Dr. Poynton referred to hematuria, without other symptoms as sometimes met with in infantile scurvy. In malignant endocarditis, renal hemorrhage also occurred not merely from infarcts but from toxic nephritis. Mr. Langton, president, referred to the rough clinical diagnosis that, when blood was intimately mixed with the urine, it was probably from the kidney or ureter; when appearing at the beginning of micturition it was more likely from the urethra. In a case with all the symptoms of renal calculus, he had explored the kidney without result, but the man completely recovered, and was quite well 18 years afterwards. He thought hematuria more frequently due to small than to large stones.

Mr. Hugh Lett has communicated to the Medico-Chi. an analysis of 99 cases of inoperable mammary cancer, treated by oophorectomy. Marked improvement followed in 23.2 per cent., less improvement in 13 other cases—that is, 36.4 per cent. were benefited. Excluding patients over 50, this percentage rose to 41.3. In successful cases the benefit had been great; in no case was a cure obtained. In one, the patient was alive and well five years after operation; four others had good health for four and one-quarter years, or more; in fifteen the improvement lasted over a year. The results were slightly better when thyroid extract was given.

Mr. Bruce Clark showed a patient now well, five years after operation. In no other case had the patient survived more than three years, but in all some improvement had followed. He never resorted to the treatment except in inoperable cases.

Mr. Stanley Boyd thought chronic cases were most favorable. In one of his own the cancer had existed four and one-half years before operation, and the patient lived twelve years afterwards. In a case of Dr. Herman's it had existed six and one-half years before oophorectomy, and the patient lived twelve years after. He thought other records showed the importance of the time that the cancer had been present before opration. In these chronic cases the resistance of the patient was high. He had two or three times removed both breast and ovaries, and his impression was in favor of the combined operation.

Mr. J. Hutchinson, Jr., mentioned the difficulty of obtaining evidence of duration, and said an intelligent woman with a large cancer had told him it had lasted a week. He also referred to the spontaneous disappearances of cancer which sometimes surprised. He thought a time limit could not be fixed. He had removed a breast for cancer and the disease returned ten years later.

Dr. Herman said those cases did best which were operated on about the menopause. Thyroid treatment he thought beneficial.

Mr. McAdam Eccles attached great importance to the nature of the carcinoma and the rapidity of growth; also to the microscopical examination of the ovaries removed, as well as to the shrunken growth. A patient of his lived twenty-six months after oophorectomy, but had been practically well for sixteen months.

Mr. Pearce Gould referred to the fallacy of the statistics of collected cases, only successful ones being published as a rule. He had only seen one case with a striking result, and in that the patient unfortunately died from intestinal obstruction. Sections of the shrunken growth showed atrophy and fibrosis of the cell elements. He did not feel able to press the operation on patients. He had seen several cases of spontaneous arrest. Until the nature of cancer is known, it is impossible to see what physiological means can account for these arrests, but he looked forward to their discovery and employment.

The 13th expedition of the Liverpool Tropical School has returned. The members, Drs. Boyce, Evans, and Clarke, were entertained at a luncheon on Monday, by Sir Alfred Jones, who, in his speech, suggested that such work should be invested with more of an international character. If other nations interested in West Africa were to join, the results would be still more successful. Dr. Boyce said this was only a segment of a greater expedition all of which was working to the same end. A telegram from Princess Christian was read accepting the position

of Honorary President of the Liverpool School, and requesting to be kept informed of the progress of its work.

Details of the arrangements for the meeting of the British Association in South Africa were issued yesterday. Prof. G. H. Darwin is president-elect. Opportunity will be afforded for visiting the battlefields, the Victoria falls, and other places of interest. At the wish of the local bodies competent investigators will deliver addresses on local problems. Colonel Bruce will deal with bacteriological questions of practical importance to South Africa. Others will discuss geological and archeological questions. The sectional meeting will be in Cape Town (three days) and Johannesburg (three days).

OUR PARIS LETTER.

(From Our Special Correspondent.)

ELECTION OF PROFESSOR RECLUS TO THE CHAIR OF THE SURGERY —THE ASSEMBLY OF THE MÉDAILLE D'OR [illegible] ON OF M. CHAMBERLAND AND PROFESSOR POIRIER—TRACHEO-BRONCHO-ESOPHAGOSCOPY—RADIOGRAPH OF A FRACTURE OF THE HUMERUS—AUTOINOCULATION OF SYPHILITIC CHANCRE —THE AMOUNT OF CARBONIC OXIDE CONTAINED IN A LOCALITY—DEATH OF DR. LECORCHÉ.

PARIS, January 30, 1905.

THE Faculty of Medicine de Paris has just elected Dr. Reclus as professor of clinical surgery. This learned man who only a year ago was appointed professor of operative medicine has attained more rapidly than would seem possible the chair of clinical surgery at the Hôpital de la Charité, left vacant by the death of Professor Tillaux. Professor Reclus began his course on January 27, by delivering a eulogy on his predecessor, Tillaux. At this time he gave full evidence of his powers as a finished orator, which makes him so pleasing to an audience.

At the Assistance Publique, two sets of judges have just been elected to decide on the merits of the candidates, internes of the Paris hospitals, who desire to obtain the médaille d'or de l'internat. Every year a certain number of medical internes of the Paris hospitals, having completed their service of four years in the city hospitals, are admitted to this assembly which offers two gold medals. One of these medals is given to an interne in medicine, the other to an interne in surgery and obstetrics. One test that is given to these candidates consists in the delivery of a memoir on a scientific subject to be chosen by the interne himself; besides which, there are two other tests, one a written, the other an oral examination.

Professor Chamberland has just been elected to the Academy of Medicine to succeed Professor Duclaux, deceased. The important work of this distinguished man in the domain of bacteriology at the Pasteur Institute is well known. Guisez recently read before this body a very interesting work on the general results obtained by the method of tracheobroncho-esophagoscopy, describing the numerous advantages and the improvements that are due to this method, which he was the first to use in France.

Professor Poirier has just been nominated in the section of anatomy to succeed Professor Marey, deceased. Poirier was for ten years director of the anatomical work in the Faculté de Médecine, and was appointed professor three years ago. The Academy in electing him one of its members, shows the esteem in which they hold his works, among which his "Anatomie humaine" in five volumes is especially worthy of mention. It has become a genuine classic.

At the same meeting Auguste Broca presented the radiographs of a fracture of the upper extremity of the humerus in a small girl of ten years. The fracture was recognizable by the classical signs also; it was located about two cm. below the cartilage covering the head of the bone. The child had been treated by the application of Hennequin's apparatus, and the radiograph demonstrated that the reduction of the fracture was not perfect by this method. Under these conditions, after chloroform anesthesia, Broca had extension made by an assistant, while he exerted in the axilla a direct propulsion from within outward, on the diaphyseal fragment. When he felt the reduction of the fracture with his fingers, he immobilized the shoulders and the arm, with the forearm at a right angle, in a large plaster apparatus The radiograph showed an absolutely perfect result.

At the meeting of the Société Médicale des Hôpitaux, Queyrat presented some extremely interesting cases demonstrating indisputably the possibility of autoinoculation of the syphilitic chancre. It is well known that one of the dogmas on which the specificity of the syphilitic chancre rests, is that it is not inoculable in the patient who possesses it. On this point almost all syphilographers agree. But Queyrat reports several experimental results tending to prove the theory that syphilitic immunization is progressively acquired and that it is positive only [illegible] about a month after the inoculation. The author has made a series of experiments directly on man by practising the autoinoculations on syphilitic subjects. Out of thirteen cases he has obtained positive results three times. He presented at the same time to the society a female orang-outang, in which Metchnikoff, of the Pasteur Institute, produced several successive syphilitic chancres by [illegible] first inoculated on the left eyebrow from a syphilitic chancre of the macacus; ten days later, it was inoculated anew with the virus of a human chancre on the right superciliary arch and eyelid. The first inoculation gave rise twenty-six days later to a large syphilitic chancre; the second inoculation had as a result four syphilitic chancres, which appeared after twenty days of incubation. This experiment of Metchnikoff's appears to prove that the immunization of the organism [illegible] is not established so rapidly as has hitherto been believed.

At the Académie des Sciences, Professor Armand Gautier showed some apparatus, the outcome of researches by Albert Lévy and Bécoul, which was made for the purpose of determining approximately the quantity of oxide of carbon that the atmosphere of any locality can contain. This apparatus is based on the property of carbonic oxide which decomposes iodated substances, thus setting iodine free. The air to be examined is conveyed into the apparatus where it is intimately mixed with an iodic solution heated to 60° C. If the air contains oxide of carbon, it will set free iodine in amount proportionate to that of the oxide of carbon contained in the air. In order to measure the quantity of iodine set free, and consequently the quantity of carbonic oxide contained in the air, we pass the air into a tube containing chloroform; this will be colored rose to a greater or less degree. It is sufficient then to compare the coloration obtained with that of a series of test-tubes containing chloroform and tinted with carbonic oxide in definite proportions, in order to determine the amount of poisonous gases in the air examined. This method has a practical application, for it has been shown by it that the troubles experienced by the employees in the crematory of Père-Lachaise, are due to the poisonous action of the gas liberated by the combustion of coke.

Among the noted men who have recently died should be mentioned Dr. Lécorché, professeur agrégé at the Faculté de Médecine, honorary physician to the Paris hospitals. He was the author of several important works, among which are one on gout, another on diabetes, and a third on diseases of the kidneys.

OUR LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

SMALLPOX [illegible] WORK OF THE MEDICAL SOCIETY [illegible] OF LEPROSY—FISH-EATING THEORY [illegible] FOR THE NON-CONTAGIOUSNESS OF THE DISEASE—NEW BRITISH SEAMEN'S HOSPITAL—TURKISH QUARANTINE—DEATH OF DR. BOURNOWSKY

CONSTANTINOPLE, January 20, 1905.

FROM a medical point of view there has been little of interest doing in Constantinople during the last few months. Public hygiene has been much written about, but all the writings amount to paper plausibilities in the form of instructions, recommendations, and the important action of "trades," *i.e.* a putting forward of arguments in favor of anything possible or impossible.

Smallpox is prevalent, as usual, at this season; vaccination and revaccination are not only recommended but commanded. The intelligent of the population anticipate the recommendations and instructions, and there the matter ends, to be taken up again next season. The conditions favoring the propagation of infectious diseases are always and everywhere present in the Turkish Empire, and epidemic recrudescence is a matter of course.

Vaccination is a spasmodic and seasonal performance. It is, therefore, not necessary to assume fresh importations of the disease to explain the perennial recurrence of smallpox. American and European statistics with reference to [illegible] with its occurrence in any large town in Turkey. The disease never dies out. From early winter to spring it is active; in summer it is more quiescent. On the strictly geographical distribution and periodicity of smallpox Turkey throws no light. New centers of infection are continually being produced, as may naturally be expected from the wandering and, at times, the gregarious massing of certain classes of the population in the many "Khans" for travelers from the interior, where smallpox prevails, and who are clothed with materials to which infection clings.

The winter session of the Medical Society has so far been marked by good work, *i. e.* by practical demonstrations. The most interesting subject, however, is that of the contagion of leprosy, which was before the Society some years ago. Several commissions were appointed to examine and report, but the results of their labors are apparently still in abeyance.

At the International Medical Congress of Madrid, Dr. Zambaco Pacha, who is, and has been always, an anti-contagionist with regard to leprosy—made a communication on the subject, which appears not to have received the attention it deserved, nor what the learned Pacha anticipated. However that may be, the communication has been followed up by an annex communication—"Epilogue Annexe de la Communication faite àu Congrès International de Madrid," in which Dr. Zambaco, after some years, reviews the course of his studies and arguments, reexamines the surviving lepers he has watched for many years, and the new cases which have occurred more frequently in the newly established clinics during those years, and with the collaboration of numerous colleagues who were well placed and qualified for the work, ever practising in the countries and localities where leprosy more or less abounded, and who devoted long investigation concerning the contagion and heredity of leprosy in this part of the East. The *pros* and *cons* are given fully and in detail. "For 32 years," writes Dr. Zambaco, "I have given myself to the special study of lepers, and in the midst of their surroundings, without ever having met one single case of contagion. My numerous colleagues, whether in the leprous districts of the Ottoman Empire, or otherwise, have never shown me an example of transmission by means of intimate contact, even by conjugal relations, over periods of 15 to 20 years, and beyond. Bacteriology, however, having shown the bacillus of the disease, it is generally understood that leprosy should be fatally and everywhere contagious. According to me, the question cannot be resolved except by the attentive and prolonged study of the sick, *i.e.* by clinical study, for there are many secrets of the mode of propagation of leprosy that even bacteriology has not been able to penetrate."

The facts advanced and the evidence adduced by our learned and distinguished colleague are worth careful perusal and study of both contagionists and non-contagionists. His studies cover a large field of inquiry; they indicate the localities where the subject may be carefully studied under various and different conditions of national and social life, climate, dietary, the relations of the sexes, marriage, and offspring. Turkey, European and Asiatic; Greece; the islands of the Archipelago; Egypt, Syria and Palestine, in short every place where leprosy exists, has in some measure and manner, given facts in support of Dr. Zambaco's views of heredity of leprosy, but not of contagion, whilst his numerous colleagues—men of learning and distinction—are singularly unanimous in support of his views.

With reference to the fish-eating theory of the cause of leprosy, Dr. Zambaco states (on the authority of Dr. Karamarondi, one of his collaborators) "that, in the island of Samos, the Lenten session and fasts of the Orthodox give 150 days a year," and asks, "what diet is observed during these days of abstinence? Dried or salted fish, and infected, frightfully stinking, which the people moisten with "eau de vie" at one piastre the litre, and with a local wine containing from 20 to 30 per cent. of alcohol. Such a diet and such a hygiene, under the rays of a subtropical sun, are favorable to all cutaneous diseases—favorable to the culture of the bacillus—yet, in no way, do these conditions appear to influence the contagion of leprosy." The islands of Leries, Volo, Libassia, Platanos, Kerassia, Gano, and Thassas, present similar conditions, yet not one case proving contagion has been established. Egypt and Palestine, which, from time immemorial have been endemic centers of leprosy, especially Jerusalem and Damascus, are also considered in detail. Dr. Zambaco lays stress on the reports of Dr. Engel Bey, who, though a contagionist, whilst insisting on the antiquity of leprosy in Egypt in the time of the Pharoahs and other neighboring peoples, is astonished to see that, although no measures have been taken even to restrain the malady—the lepers living pell mell with the inhabitants—the number should be relatively so small, and that strangers coming to Egypt are not infected in the very cradle of leprosy, where the most favorable conditions for its propagation are reunited—Alexandria being a striking proof, as there live many Europeans, and no leper among them—though there are some from Crete. Further, that Dr. Engel Bey, estimating the number of lepers in Egypt at 18,000, has not in twenty-two years seen a leper contaminate either a native or a foreigner, though lepers everywhere abound, which statement is confirmed by other physicians practising there, clearly proving that the bacillus is not aggressive in Egypt.

The leper house at Scutari, which is supposed to be for isolation, is adduced as a proof of the non-contagiousness of the disease, "for there strangers enter freely into the chamber of the lepers, and remain there, eating and drinking with them from the same vessels, breathing for hours the supposed-to-be-infected air, even resting on the beds without thought or fear of contagion, which is, indeed, rare, and under exceptional conditions—a mere coincidence." A certain class of Spanish Jews, driven by persecution from Spain, took refuge in Turkey in the reign of Bayazid II. Since then they fixed themselves at Stamboul, and in the province of Salonica. Now, these Spanish Jews only among the native races of Constantinople count many lepers. They preserve their leprosy by ancestral heredity. They had it already in Egypt under the Pharoahs—the cradle of leprosy—before the Exodus, and imported it into the desert and wherever they established themselves. Besides these Jews of Hebrew origin—there are at Constantinople Jews of Polish, Russian, German, Hungarian, Roumanian origin, abounding in quarters of Galata, miserable and sordid, yet they count not a single case of leprosy. They are different in origin, being Tartar, German, clans of Indo-European race, and do not suffer from leprosy as do their coreligionists from Spain, who have been in Constantinople for 400 years, and have always numerous cases of leprosy amongst them, and are in continual communication with the other elements of the population, without communicating leprosy to them. Hence, concludes Zambaco Pacha, the leprosy of the Spanish Jews is due to ancestral heredity—ethnical—from their direct descent from the Hebrews of Moses.

The learned Pacha then gives an historical sketch of the Jewish race, bearing on the subject of leprosy, which is full of interest. In Egypt, Constantinople, and elsewhere it is notorious that the lepers mix in general society. They are venders of vegetables, fruits, milk, and other merchandise. They are in domestic service, mix together in churches, cafés, and places of public entertainment, and are not generally avoided unless their appearance is repugnant from open sores. Such is the summary of the "Epilogue Annexe" of Dr. Zambaco Pacha. The statements and facts are brought forward as a protest against the conclusions of the Berlin Conference of 1897, proclaiming the contagiosity of leprosy as "always and everywhere—even in Central Europe—equal to that of smallpox and plague."

Your correspondent, who has practised in Egypt and Turkey for thirty-six years, who has visited most of the leper establishments, and taken an interest in the subject of leprosy, has arrived at the conclusion that the disease—the bacillus notwithstanding—is feebly, if at all, contagious in these parts of the East, and that the evidence of heredity is strong.

The new British Seamen's Hospital was formally opened on January 18. It is a solid construction, erected on the old site. It has accommodation for forty patients and is in all respects up to date. It is lighted by electricity, and has an electric lift; is elegantly furnished. The general and private wards are spacious and airy. The operating theater is a marked feature of the hospital, is supplied with the latest appliances for aseptic and antiseptic surgery, and has a good stock of instruments. After a short religious service, the hospital was declared to be open by the Lady Susan Townley, wife of H. B. M.'s chargé d'affaires.

The operations of Quarantine appear to be satisfactory, since no complaints are made by the shipping interests. In regard to quarantine, Turkey has fallen into line with the other Powers, instead of as formerly being passively obstructive.

Dr. Boukowsky Pacha, the chief government chemist, and head of the hygienic service, died a few days ago. His services were much appreciated by the Imperial Government during the plague and cholera epidemics in Syria and Asia Minor, where he organized a special service.

A Human Toxophile.—At present there is in Glasgow one Captain Vetrio, who styles himself the "poison-proof man," giving exhibitions in one of the places of entertainment of his ability to swallow lethal doses of certain poisons, such as strychnine, phosphorus, and so on, with apparent impunity. With these we are told he varies his *menu* by eating glass and flower-pots! Before he made his first public appearance, a number of medical men responded to his invitation to meet him in the Windsor Hotel, where he swallowed half a grain of strychnine in their presence, and also, we are told, partook in quick succession of considerable doses of paris green, blue indigo, verdigris, and so on, without evil effects. This demonstration, we are further told, concluded by Captain Vetrio's eating a considerable portion of a stick of phosphorus. He invites medical men to bring their own poison. A letter appeared in the *Glasgow Herald* pointing out the responsibility resting with any medical man, from a medicolegal standpoint, who should, in the event of this man's death, have supplied him with the poison.—*Medical Press.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, February 16, 1905.

Perilous Calms of Appendicitis.—Robert Wallace Hardon sums up his paper as follows: Defervescence of symptoms and apparent better condition of a patient do not always mean recovery, but may be the forerunner of a more dangerous condition. There being no specific for the disease, no matter what treatment is used, the one who procrastinates should shoulder the responsibility for the death. When a clear diagnosis is made, but one treatment should be advised, that of operation as soon as possible under the conditions, or the golden opportunity may be forever gone. The physician who does not explain the great dangers of delay and the small comparative danger of operation is doing his patient a serious injustice, which often leads to fatal results. Operation at the proper time usually greatly shortens convalescence, and eliminates all danger from this cause hereafter. Procrastination is the greatest cause of surgical deaths, operation often being performed as a last resort, when but little hope of recovery exists.

The Prognosis of Epilepsy.—William Aldren Turner declares that sex plays little part in the general prognosis of epilepsy. As to the influence of sex upon the mental condition in epilepsy it appears that a larger percentage of women escape the deteriorating influence of epilepsy upon the mind than men, but that when dementia develops, a rather higher percentage of women are affected. The hereditary maladies taken into consideration in the writer's investigation were epilepsy and insanity. The conclusions in this regard are that there is as great a chance of arrest of epileptic fits in those who have, as in those who have not, a known family history of epilepsy. In those who have an hereditary history, the chances as to whether the fits become arrested, improved or confirmed, are in any given case about equal. As regards general improvement, more is to be expected in those who have no hereditary disposition, while a considerably smaller percentage of confirmed epileptics is to be found among those who have no family predisposition to the disease. A family tendency to either epilepsy or insanity, although it offers no obstacle to the arrest of the seizures in favorable cases, materially increases the likelihood of the disease becoming confirmed and the supervention of dementia. As to the influence of age at the onset of the disease, the writer concludes that epilepsy commencing in infancy and childhood is the least favorable for the arrest of the fits, and the most favorable for the production of the confirmed disease. The common type of the disease, or that commencing during puberty, is the most favorable form of epilepsy both in relation to the arrest of the seizures and the absence of mental infirmity. Adult epilepsy is unfavorable. Senile epilepsy is tractable. Generally speaking, the earlier a case is brought under systematic treatment, the more hopeful the prognosis and the greater the probability of improvement. The longer the interval between the attacks, the greater the prospect of arrest or improvement. Major attacks are more readily influenced by drugs than are the minor seizures. As to the cure of epilepsy, the writer speaks of 15 cases in his series out of a total of 147, which have been observed for a period of at least nine years, as being arrested for this time. This makes a percentage of 10.2 cures. It may be taken as a general rule that a cure of epilepsy has been established after an arrest of nine years. Nevertheless, a very small percentage of cases relapse after that period.

A Study of the Birth-Rates, General Death-Rates, and Death-Rates from Cancer for the New England States for the Year 1900.—William F. Whitney states that when compared with foreign countries our birth-rates are low. In a comparison of the death-rates for Massachusetts for the years 1850, 1875 and 1900, it has been found that a marked improvement has taken place in those of the earlier periods of life. From five to ten, the three more thinly populated states have a slightly lower death-rate than the others; from ten to forty there is practically no difference. From that on, each separate decade appears to be decidedly in favor of the more rural communities. However, when the ages are taken in the aggregate these differences are lost sight of. As to the death-rate from cancer, it appears that there has been a gain all along the line in each of the states. Massachusetts, however, is far below the others. It is scarcely credible that the greater gain in the other states is due to a real advance in the disease itself, but rather to more careful registration, which has now brought their vital statistics up to the standard of Massachusetts. The writer concludes by saying that it will probably be many years yet, even with modern accuracy, before the truth as to the alleged increase of cancer will be known. It is possible that it will then appear that at the end of the last century we were on the crest of a cancer wave, to the apparent height of which more accurate diagnoses and registration had greatly contributed, and the commencing secession of which is foreshadowed by its slight increase in Massachusetts for the quinquennium of 1900.

New York Medical Journal, February 18, 1905.

Locomotor Ataxia Successfully Treated with Ultra-Violet Rays.—J. M. Liebermann calls attention to the importance of diagnosis in the pre-ataxic stage and reports his results in the treatment of 36 cases of the disease. Of these 34 were males. The ages varied from 24 to 63 years. Four patients were restored to good health and were able to resume their usual occupations. Twelve were greatly benefited, their power of coordination restored, pain abolished and they became able to use unassisted the upper and lower limbs. In 18 the disease was apparently arrested, with hope of further improvement. Two died during treatment, one from lobar pneumonia and the other from erysipelas of the head. The author has employed local cataphoric dehematization before applying the ultra-violet ray. The lamp for the latter was excited by a static machine, the large Leyden jars being used as condensers. Sittings have been given thrice weekly from ten to thirty minutes. A warm half-bath has been advised together with light massage each night. Static electricity by means of the Morton wave current or wooden bunt has been given daily for from fifteen to twenty minutes. The author does not claim that this plan will cure every case, but feels much encouraged from results thus far obtained. He notes that the application of the ultra-violet ray to dehematized tissues should be made with great care and judgment. In his opinion it is a very powerful remedy and should never be applied to more than two localities at each séance, and the area should be varied so that every day a different region of the cord is treated. He divides the spine into three regions, cervical, lumbar, and sacral, treating these alternately or in rotation.

Fibroma of the Vulva.—T. S. Burr reports a case of this nature. He has found but comparatively few cases in the literature of gynecology, though he sees no reason why this region should be exempt on histological grounds. His own patient was a multipara of forty-two years. Several small masses had been removed from different vulvar sites during the previous eighteen years. When first seen by him, the patient presented four growths, all in the left labium majus, varying in size from a hickory nut to a large walnut. Operation was by enucleation and elliptical incision. Recovery was without incident. Eighteen months later there had been no recurrence. The author discusses the histology of these growths and the differential diagnosis of vulvar neoplasms.

Medical News, February 18, 1905.

Intrapleural Complications in Pulmonary Tuberculosis.—S. G. Bonney has observed over fifteen hundred cases of pulmonary tuberculosis in private work. He calls attention to several complications of this disease, the first one being pleurisy with effusion. This condition is far more frequent than is generally supposed. This is due largely to the fact that it is often overlooked. Sometimes small effusions—and even moderate ones also—exist without any rational symptoms to suggest their presence. The writer believes in the practice of ordinary aspiration in a case of pleural effusion of any nature and extent with any combination of rational symptoms, if the indications for its removal are sufficiently clear. A subsequent line of treatment can be safely and intelligently followed with the additional information secured through the gross appearance and the bacteriological examination of the exudate. The employment of the exploratory puncture for diagnostic purposes only, is, however, to be condemned. Ordinary aspiration when once practised should be repeated at intervals as long as there are valid indications for it, and it should be suspended whenever such conditions cease. If the effusion is purulent, the discussion comes under the head of empyema. The writer's custom in the empyema of consumptives, especially if it is not too far advanced, is to let it alone unless there is some special indication for interference. In such a case, simple aspiration is first employed. If this is not sufficient, syphon drainage should be instituted. Not until this proves unsatisfactory should there be resort to radical measures. The one exception relates to thoroughly septic cases with advanced tuberculosis infection and preferably with well circumscribed empyema. Such a condition demands free opening and thorough drainage at once. As to pneumothorax, the prognosis of acute cases must be regarded not only from their present condition but from the basis of their possible chronicity. In cases of open pneumothorax, the indications for treatment consists solely in excessive stimulation for a few hours. In urgent cases, besides stimulation, aspiration of the air is indicated. This is applicable only to cases of the valvular type permitting the ingress

t air with each inspiration, but preventing its exit upon expiration and occasioning a positive hyperdistention in the pleural cavity. The prognostic influence of closed pneumothorax upon pulmonary tuberculosis, if unassociated with liquid, is not necessarily unfavorable. Indeed, actual benefit may result from the compression. The danger lies in the opportunity for the development of infection and the transformation of the condition into pneumopyothorax. This latter condition is likely to be unrecognized without a thorough and comprehensive chest examination. It is chronic. Aside from such considerations as hyperdistention, the prognosis is to a great degree, dependent upon the degree of sepsis existing, if any is present. Unless the gravity of the symptoms demand interference, it is well to let the patient alone. If, however, treatment is indicated, occasional aspiration, syphon drainage, and finally the permanent opening of the pleural cavity, may be necessary.

Case of Primary Malignant Tumor of the Lung.—Maurice Packard reports this case. The patient, a man fifty-five years old, began to be troubled with cough and pain five years before he presented himself at the clinic. There was no expectoration at first. Three years later, mucous expectoration appeared and gradually increased. Dyspnea became more intense and permanent. The expectoration became bloody. His weight kept constant during all this time, and he did not suffer from night-sweats or fever. The bowels were regular, and micturition normal. The patient denied ever having syphilis or any venereal disease. There was no trace of cancer or tuberculosis in the family. On examination, no enlarged glands could be felt in the cervical, axillary, epitrochlear or inguinal regions. Both jugulars were enormously dilated and tortuous. The superficial veins of the chest and upper part of the abdomen, especially on the right half of the trunk, were also greatly dilated and tortuous. There was a slight superficial edema of the right chest. The space above and below the clavicle was rather full. Respiratory motion was much reduced in the right thorax. On percussion, nearly the whole right chest was absolutely flat. Over the same area pectoral fremitus was completely absent. The voice was diminished. There were no râles. An aspirating needle introduced into the dull area seemed to enter solid material. A slight leucocytosis was present. No tubercle bacilli, elastic fibers or particles of tumor could be found. Careful search for actinomyces, and other abnormalities proved negative. The stomach examination showed the presence of free hydrochloric acid and the absence of lactic acid. The diagnosis of a primary neoplasm of the right lung was made. The patient remained under observation for two months, during which time the disease progressed with great rapidity. The patient died suddenly from a profuse hemorrhage. Autopsy revealed the presence of a typical flat-celled carcinoma in the primary growth, as well as in the metastatic deposits.

American Medicine, February 18, 1905.

Kidney Diseases Requiring Surgical Interference.—J. M. Baldy reports two cases of floating kidney, one of cystic kidney and adenoma, one of tuberculosis of the right kidney and ureter and one case of surgical kidney. In none of these five cases were the symptoms such as to draw attention directly to the diseased kidney, and yet all five patients were cured by operation. Baldy has often noticed this lack of prominence of the symptoms direct from the kidney and the chance of their being overshadowed by symptoms coming apparently from other organs. In many cases the patients have been sent for other troubles and their physicians were surprised when told of the true situation. In ordinary cases the kidney lesion should be readily detected; the diagnosis is not so very difficult, at least for a suspicion, if time be only taken for the investigation. Mistakes in diagnosis in the hospitals are almost always due to being tempted to operate the day after the arrival of the patient, because both the doctor (who comes a long distance and must return) and the patient desire it, and unless the kidney symptom is sufficiently prominent to draw attention at once at even a casual examination, we are tempted to yield.

The Efficiency of Copper Foil in Destroying Typhoid and Colon Bacilli in Water.—Henry Kraemer carried out a series of experiments for testing the efficiency of the copper method for the purification of drinking water. The experiments were made mostly with copper foil rather than copper sulphate. It was found that in every instance colon and typhoid bacilli were completely destroyed in less than four hours by placing strips of copper foil in water containing pure cultures of these organisms. In the duplicate experiments, namely, in those in which no copper foil was used, it was found that the organisms persisted and continued to multiply even for sixty days. Kraemer considers it extremely fortunate that in the copper treatment of water a method has been devised which is so effective in destroying intestinal microorganisms and which can be applied so easily on a large scale and so safely by the average householder. The method suggested for domestic purposes consists simply in placing a piece of copper foil 3½ inches square in a quart of water, allowing this to stand from 6 to 8 hours, or over night, at the ordinary temperature, and then removing the foil or drawing off the water.

Classification of Gastric Ulcers.—A. L. Benedict urges the same general use of the term ulcer in the case of the stomach, as of other parts of the body, first because there is no unanimously accepted definition of gastric ulcer and, second, if there were, it would be impossible to make all cases correspond to it. Without hemorrhage or opportunity for inspection, the diagnosis of ulcer can only be tentative, but a diligent search should be made for small hemorrhages. If hemorrhage is clinically demonstrated to be from the stomach, it almost always means an ulcer in the proper general sense of a solution of superficial continuity. He classifies ulcers of the stomach, including certain conditions associated with hemorrhage, as follows: (1) Peptic ulcer, the most frequent, occurs in patients who do not have apoplexy, thrombosis, embolism and organic vascular lesions elsewhere and in whom a primary organic basis for the necrosis is untenable. He asserts that the digestion of the necrotic area is not simply an erosion by excess of HCl and he is also skeptical as to the uniform association of hyperchlorhydria and peptic ulcer. (2) Superficial erosions due to chemic and thermic caustics. (3) Ulcers due to vascular lesions, occurring in syphilitics and in elderly persons. He reports such a case in detail and alludes to others. (4) "Catarrhal" ulcers, analogous to eczematous ulcers of the skin, not strictly separable from the foregoing, but without definite, conspicuous, local vascular lesions. (5) Varicose ulcerations, due to venous obstruction and, practically, almost always to hepatic sclerosis. (6) Toxemic diapedesis, as in scurvy, purpuras, etc. (7) Vicarious menstruation. (6 and 7 are not true ulcers.) (8) Gangrenous ulcer. Such cases usually illustrate 3 and 4 and, still more frequently, cancerous ulceration and do not really constitute a distinct, pathologic type. (9) Phlegmonous ulcers. Unless due to pyemia or subphrenic or other abscess contiguous to the stomach, such ulcers are usually due to iodin, poisoning. (10) Specific ulcers include exanthematous, pneumococcic, tuberculous, syphilitic, actinomycotic and similar conditions due to special germs and, by an extension of terms, those due to the breaking down of neoplasms, especially cancer. (11) Traumatic ulcers, due to foreign bodies, hard particles in food, crushing injuries, gross parasites, etc.

Strangulated Hernia in the Very Old.—D. C. Peyton believes the process of inflammation of the imprisoned loop offers a satisfactory explanation of the cause of strangulation. The obstructive venous congestion is the first step in the inflammatory process, and this inflammatory process, begun in obstruction, by pressure engorgement is the result of the increased activity and virulence of B. coli communis, and several varieties of the staphylococcus and streptococcus, which, if not arrested, results in gangrene and death. The treatment is operative only, and the earlier the operation the more satisfactory will be the results. He believes taxis is not only a mistake but a menace to the life of the patient and should never be resorted to. Extreme age should be considered a bar to operation, the patient's general condition should be considered only. In the very old, the minimum degree of general anesthesia is desired, so that the injection locally of Schleich's solution, along the line of incision has proved of great advantage by reason of its local effect. When the heart is weakened, the use of oxygen alternating with ether is an excellent precaution. Old people do not stand confinement to bed, so it is of greatest importance to get your old patients out of bed and into an invalid chair in not longer than four or five days. Turn them to the sound side in 24 hours after operation. Oftentimes success may be determined by this fact. Less than a year ago Peyton operated on a woman of 84, less than 8 hours after strangulation of a femoral hernia. The sac was opened, and extensive adhesions broken up, the omentum well pulled down, ligated and cut off, the intestine returned to the cavity, and the ring closed with the pursestring suture. The patient made an uninterrupted recovery; was out of bed and in an invalid chair in four days, and in 17 days walked.

The Journal of the American Medical Association, February 18, 1905.

Chylous Ascites with Eosinophilia.—L. Napoleon Boston reports a case of true chylous ascites occurring in conjunction with tuberculosis of the peritoneum, and points out the diagnostic features of this form as contrasted with those of pseudochylous effusion. In the latter the emulsion is less perfect and contains large numbers of epithelial cells and granular débris in various stages of degeneration and there are few fat droplets. It also collects more slowly, does not contain sugar as a rule, is not affected by diet as to the

amount of fat contained or as to its odor, and a heavy sediment is likely to collect at the bottom. In true chylous effusion the opposite conditions are observed and there is no layer of fat globules such as may occur in the pseudochylous form. He analyzes 126 cases reported in the literature as regards sex, age, existing abdominal conditions, treatment and results, as well as their exciting causes, such as malignant disease, tuberculosis, cardiovascular conditions, liver affections, puerperal sepsis, congenital cysts, filariasis and injuries to the thoracic ducts and receptaculum chyli by obstruction or trauma. Sixty-one of the cases were females, fifty males, and in the remainder the sex was not given. The larger number of cases occurred after the thirtieth year of life.

Tuberculosis Sanatoria.—F. L. Hills outlines the essentials of sanatorium treatment of pulmonary tuebrculosis. He would make six months the minimum term of residence, excepting in the very incipient cases. He insists on the importance of following up the cases after discharge; this would give us valuable facts as to the ultimate results of sanatorium treatment, the percentage of permanent cures, duration of arrests, and other facts of importance for the guidance of future therapeutic work.

Intermittent Exophthalmos.—W. C. Posey reports an instance of this rare affection, of which he is able to collect only 39 cases in the literature. He thinks that it is probably more frequent than supposed. Its characteristic symptom is the pushing or falling forward of the eyeball when in a dependent position or when the return of blood from the head is interfered with by holding the breath, pressure on the jugulars, coughing, sneezing, tight collars, etc. The proptosis is usually unaccompanied by pain and the patient may be unconscious of it. Vision may be unaffected or permanently impaired or lost. Generally it is only impaired during the protrusion. The diagnosis is easy and the prognosis is generally good. The patient should avoid excessive strain and anything that causes the eye to proptose. Ordinarily operation should be advised against, though where hemorrhage has occurred and vision is threatened Hitschmann's counsel to lay bare and resect the affected veins may perhaps be followed, Krönlein's operation being resorted to if necessary.

Locomotor Ataxia.—Guy Hindsdale reports an apparently typical case of tabes without positive syphilitic history treated by rest, massage, electricity, and educational movements and, internally, nitrate of silver and extract of belladonna (as there was intolerance for the iodides). The symptoms gradually disappeared. In eight weeks there was an increase of nearly forty pounds in weight. The urine, which had contained albumin and casts, became normal, and in three months he returned to his former occupation apparently well. After three years he came again under treatment with similar symptoms. His weight was reduced to 104 pounds. The same treatment, with the addition of hypodermic administration of mercuric chloride, 1-20 grain twice daily, was employed with like results as in the first attack. In nine weeks he had gained forty-six pounds. The case is reported as of interest in showing the value of the rest treatment when employed sufficiently early with electricity and massage or exercise. While a cure is not claimed in the case, there is at latest reports improvement in all lines.

The Lancet, February 4 and 11, 1905

A Case of Typhoid Fever Presenting Some Unusual Features.—The case is reported by Kenneth Anderson. The peculiar features of the case centered first of all about the diagnosis. The disease began with a rigor and acute localized nephritic pain. Cystitis also came on while certain chest signs led to a suspicion of tuberculosis. Widal's reaction, however, was positive, and the later appearance of spots, the enlarged spleen and the character of the stools led to a diagnosis of typhoid. The temperature subsided to normal after a run of fifteen days. There were then three relapses separated by short apyrexial intervals, and a later fourth recrudescence of fever. The discharge of a carneous mole was the first indication that pregnancy coexisted for a previous vaginal examination, had not detected any uterine enlargement, bimamial examination being hindered by rigid abdominal muscles. The foul condition of the uterine contents may have accounted for the pyrexia of the second relapse. Other points of interest were (1) The inability to continue the administration of digitalis by the mouth (called for by the weak heart), owing to gastric irritation so produced. Fortunately, the cardiac condition improved at this time. (2) The occurrence of stomatitis after the administration of mercury (given for constipation), in small doses for about three weeks. (3) The enlargement of the liver, which was present when the patient left the hospital. (4) The absence of any sequelæ.

The Prognostic Value of the Diazo-reaction in Typhoid Fever.—Basing his experience on results in sixty-five cases of the disease, J. D. Rolleston summarizes as follows: (1) In all but severe attacks the diazo-reaction tends to disappear in the course of the second or third week, this disappearance shortly preceding, or coinciding with, the commencement of lysis; (2) its reappearance during or after the completion of lysis is a warning of recrudescence or relapse, or of complications directly due to the specific bacillus; (3) a sudden disappearance of the reaction associated with a deterioration of the general condition is of bad omen; and (4) the character of the reaction is a useful check to the history.

Non-Traumatic Cerebral Hemorrhage in a Child Aged Ten Years.—H. Taylor reports the case, the patient being a little girl, previously always well, who suddenly put her hand to her head exclaiming, "Oh, my head!" gave a cry, fell down, and was in a minute or so very sick. The parents were at first inclined to ascribe the attack to overeating, but on raising her to a chair they found that "she had lost the use of her limbs." The author saw her about an hour afterwards. She had been very sick and was still inclined to retch. She was reclining in an arm-chair in a semi-comatose condition, her pupils were dilated and fixed, her temperature was 97.8° F., and her pulse was uncountable. The mouth was drawn over to the right side of the face, the head was inclined to the right shoulder, and her left leg was quite paralyzed, but the left arm was not so much implicated. Early the next morning she tried to "turn over" in bed, made an abortive attempt at vomiting, and quietly died. The father was a strongly built "workman"; the mother a weakly anemic rheumatic woman, had a large family, and one sister suffering from constantly recurring tonsilitis. A necropsy disclosed a hemorrhage which, starting from some vessel in the corpus striatum or optic thalamus, had literally ploughed its way into the right lateral ventricle, the resulting clot completely filling the cavity.

The Role of an Excessive Meat Diet in the Induction of Gout.—D. C. Watson has sought to determine by observations on animals, whether an excessive meat diet produced any specific action on the ductless glands. He finds that raw meat and water do profoundly affect the thyroid glandular system. In poultry such a diet induced a striking hypertrophy of the thyroid and parathyroid, the tissue of the former assuming appearances characteristic of simple parenchymatous goitre in the human subject, viz., great enlargement of spaces which were distended with colloid material, enlargement of the vesicle walls and in some areas, proliferation and shedding of the epithelial cells with hemorrhage into the vesicle cavities. The same diet in rats showed a diminution in the amount of colloid material, epithelial cell and connective tissue proliferation, vascular congestion and rapid degeneration of the colloid into a mucinoid substance, in other words changes suggestive of those seen in exophthalmic goitre in man. The author has no theory by which to explain the contrasted changes in the two classes of animals. He believes it possible that as one result of the excessive use of meat during recent years, there has been established in many subjects an alteration in the character of the thyroid secretion, which defect is remedied in the cases in question by the administration of thyroid gland. The adoption of this view has led him in the past year to try the effect of the administration of small doses of thyroid extract in two inveterate cases of chronic gout which had not been amenable to dietetic measures aided by skilled balneological methods. In both cases the symtpoms were relieved to a striking degree, this relief having been so far of a fairly permanent nature.

Carbonic Acid as a Factor in the Genesis of the Gouty State.—D. F. Shearer states that while it is not possible to show by direct experiment that either fibrous or muscular hypertrophy follow upon excess of carbonic acid or that the latter inhibits urinary secretion, clinical experience shows that in many patients, carbonic-acid excess will produce high vascular tension with headache, vomiting and partial anemia, and that as recovery comes on, with a soft pulse and profuse diuresis, the urine being loaded with water. These attacks may be due to excess of food, alcohol and lack of proper exercise, or the breathing of air containing carbonic-acid excess. Persistent excess may lead to chronic nephritis and arterio-sclerosis. Now, gout as well as the two diseases just named, and in fact, all so-called uric-acid conditions, are bound up with antecedent states in which the main and common factor is the carbonic-acid excess in the arterial blood. This it is which determines whether the uric acid shall be eliminated or retained. Its power to limit the water secreted by the kidneys may be overborne by the high tension in the glomeruli while still retaining the controlling influence over the uric acid. This latter, then, in this view, occupies a secondary place, it remains no longer an etiological factor but becomes merely a retained normal secretion which

under certain conditions obtains a pathological importance by being deposited in the neighborhood of a joint and becoming the active cause of a local inflammation. The primary place must be assigned to the unnatural excess of carbonic acid in arterial blood as the most potent factor in bringing about those changes which go to make up the gouty state.

The Rational Treatment of Fractures.—According to J. S. Mellish, the surgeon's duty is, after having approximated the fractured ends of the bone, to keep the circulation of the limb in a healthy condition. Hence the less splinting necessary, the better, and dependence must be placed upon rubbing and movement of a voluntary kind. When we are obliged to use a splint as with the humerus or femur or both bones of the leg, rubbing must be practiced, and the patient induced to move his joints voluntarily every day, the splints being removed for this purpose, and then replaced. The rubbing should always be in the direction of the venous return, commencing at the proximal end of the swelling in the region of the fracture, and working toward the distal end. The joints are given free play where possible, and in this way wasting and stiffness are reduced to a minimum. The patient must be persuaded to execute, while the bone is held, all the movements normal to the joints between which the fracture lies. The author considers this plan both more rational and more efficacious than to wait a conventional time after the receipt of the injury and then begin passive motion.

General Gonococcal Infection.—W. H. Wynn reports three cases with autopsy findings. The lesions and symptoms in such a state are referable to (1) direct infection with the gonococcus itself; (2) the absorption of a toxin, and (3) mixed infection with other germs. There is no longer doubt that the gonococci can circulate in the blood and produce the lesions found in the various organs. The author gives some statistics as to isolation of the gonococci in general infection, and describes the technical methods employed in studying them under such conditions.

British Medical Journal, February 4, 1905.

The Prodromal Rashes of Measles.—J. D. Rolleston believes that the frequency and diagnostic value of the prodromal rashes in measles entitle them to a wider recognition than they have at present received. Large statistics are not available. In the writer's cases the percentage of such rashes has been estimated at 42.8%. The average age of 30 patients showing a prodromal rash was 3.5 years. In the majority of these cases, this rash appeared on the first day of the disease. The following varieties of rash have been met with: Isolated macules, blotchy erythema, isolated papules, urticarra, scarlatiniform rash, and circinate erythema. The trunk is the favorite site. The postauricular region is the next more frequent spot. These rashes have a very short-lived existence, although the scarlatiniform eruptions may last for a day and a night, and the isolated macules and papules longer. The distribution of these rashes is capricious, as they may be met with in any part of the trunk or limbs. Several varieties of eruption may appear simultaneously. These prodromal rashes are strikingly free from cutaneous irritation. There is no noticeable pain nor pruritus nor any subsequent desquamation. In measles, the initial rashes do not appear to be of any assistance in prognosis. The course of the disease in ths cases in which they were noted, in no way differed from that of the cases in which they were absent. The occurrence of the rashes above mentioned, in an epidemic focus, should alone arouse suspicion of infection, and prompt examination of the buccal mucosa for Koplik's spots and the characteristic stomatitis should be made, and a close watch for any catarrhal symptoms should be instigated. In only two cases did the prodromal rash appear subsequent to the catarrhal symptoms. In some of the cases, the rash preceded the appearance of Koplik's spots, while in others the two phenomena were first observed on the same day.

Note on Lobar Pneumonia Following Measles.—F. C. Bottomley has noted in his observations that the occurrence of lobar pneumonia is more frequent than that of bronchopneumonia as a complication of measles. These cases have been marked by the same characteristics as are present in ordinary lobar pneumonia in children—sudden onset without preliminary bronchitis, and a generally favorable termination. The writer has observed thirteen cases. The ages of the children varied from one year to five years. In seven cases, the pneumonia began at the time the rash appeared. In all of the cases the pneumonia appeared before the rash had died away. One or both lobes in all cases were affected. In five cases one side only was involved. The disease in some instances terminated suddenly, in others, gradually. Rarely did the temperature exceed 102° F. All of the cases recovered, with the exception of one boy of eighteen months, who died of convulsions two days after the crisis. Bronchitis was not present in any case. During the period in which these cases occurred, only three cases of bronchopneumonia following measles were seen, and they all died. These data show the difference in the severity of the two affections. It is important to differentiate these diseases, in order to be able to give an intelligent prognosis.

Case of Precocious Puberty in a Female Cretin.—F. Wellesley Kendle reports the case of a cretin aged nine, the youngest of seven children. She presented the appearance in general of a typical cretin. But in one particular, she was different from every other recorded case. The breasts were fully developed, with well-shaped prominent nipples. There was coarse hair in the axillæ and pubes. Menstruation had begun at the age of five, and had continued at irregular intervals of from two to four months. After being on thyroid extract for six months, she has made great progress. She has grown nearly five inches in height, and has lost seven pounds in weight. She is far more intelligent. She has cut four double teeth, and is shedding her decayed incisors. The coarse hair has been replaced by a much finer growth. The skin is soft and natural, and the improvement in every respect is most marked. She has not menstruated since the thyroid extract was resumed—for at the time the child was weaned she was treated for about two years with the extract with great success, but was then lost sight of till the age of nine. The breasts are much smaller, the nipples less prominent; the hair has disappeared from the axillæ and pubes. The voice is not so deep, and the whole organism seems to have reverted to a more childlike type. The latest note was made in January, 1905. Progress still continues, menstruation has not returned. The child has grown another two inches.

Green Milk.—G. Arbour Stephens observed a woman, the mother of a baby of twelve months, whose milk was green. The milk seemed very rich in fat, and was of a duck's egg green color. The woman stated that the first lot that was drawn off was of a much darker shade of green, "like a leaf." On testing with nitric acid, the writer did not get the display of colors characteristic of this test for bile pigment. The woman was taking no medicine, nor was a belladonna plaster or paint applied to the breast. The milk was green as it came away from the breast, and not as a result of changes produced while standing. The writer asks what was the cause of this sudden change in the milk?

Berliner klinische Wochenschrift, January 30, 1905.

Intestinal Putrefaction in Catarrhal Jaundice.—Blumenthal records observations made on the urine in a case of catarrhal jaundice in order to determine the best criterion of the degree of intestinal putrefaction going on in such cases. Many authors have asserted that estimation of the ethereal sulphates in the urine gives a satisfactory index of the amount of albuminous decomposition; but others have pointed out that this method is incomplete since not all the aromatic bodies produced take this form, and advise directing the attention to some single aromatic product like indican. In the author's case, however, this would have led to very erroneous results as the indican was entirely absent on some days, and increased in quantity only during convalescence when bile began to be poured out into the intestine again. The author's view is that in order to obtain a reliable indication as to the amount of intestinal putrefaction it is not sufficient to measure any single product such as the indican, phenol or ethereal sulphates, but that in addition to all three it is necessary to ascertain the quantity of the volatile fatty acids formed in order to determine whether acid fermentation may not be taking the place of the production of aromatic bodies. In the present case the total intestinal decomposition products were much increased during the period when bile was absent from the intestine, but were especially high at the time when the secretion began to reappear.

Chemical Features of Carcinoma.—Neuberg reports some experiments which he believes will, when elaborated, have bearing on the nature of carcinomatous cachexia. In previous communications he has shown that the *x*-rays have the property of modifying the fermentative processes in carcinoma cells, and that in the autolysis of carcinomatous tissue from the liver reducing pentose is to be found, which is not the case in autodigestion of normal liver. In the present study he used not only the cancerous material found in the hepatic metastases, but also that obtained from the primary focus in the stomach. It was found that autolysis of the hepatic growth yields abnormally large amounts of pentose, whereas the material from the stomach gave the opposite result. That is, in their migration from one organ to another the carcinomatous cells either suffered a change in already existing ferments or new ones were formed. Digestion experiments carried out with liver carcinoma and lung tissue gave results exactly opposite to those obtained when healthy liver is used. The carcinomatous extract produces abnormally great decomposition of the pulmonary albumins, but is not able to

break up the resulting albumoses, which probably reach the circulation. These observations, showing the radical departures from the normal exhibited by the cells of malignant growths in regard to their enzyme content, appear to have a decided bearing on the production of cachexia.

Münchener medizinische Wochenschrift, January 31, 1905.

A Simple Test for Bile Pigment.—Presslich says that he has found a method which, for practical purposes at least, presents many advantages over the tests for bile in the urine usually employed. It consists simply in adding to the suspected urine a few drops of foaming nitric acid, and stirring. In the presence of bile pigment a well marked green color is produced. Comparison with Gmelin's and Rosin's tests showed that the author's method yields more satisfactory results. It does not react to urobilin, nor to the substances occurring in the urine of patients who have been taking rhubarb, salol, aspirin, sodium salicylate or antipyrin. The simplicity of the test, the ease of performance, and the fact that large quantities of urine may be turned green by the use of fifteen to twenty drops of the acid, so that the color is easily recognizable, render it a useful method for everyday use.

A Case of Acute Syphilitic Nephritis.—Thiemann reports what he believes is an indisputable case of acute nephritis of syphilitic origin, inasmuch as it conforms to the postulates set by Welander, Justus and Karvoner. These are: (1) that the kidneys were healthy before the syphilitic infection; (2) that the nephritic manifestations ran a parallel course with the other syphilitic symptoms; (3) that the albuminuria was cured or improved by the use of mercury. The patient was a woman of twenty-four, with a negative past history, who exhibited a typical syphilitic eruption together with generalized edema, hydrothorax and ascites. The spleen was enlarged and a well marked chancre was found on one labium. There was a systolic heart murmur, and the urine contained 1% of albumen (Esbach), and many casts. One-half gram of bichloride of mercury was given in fifty hypodermic injections, and at the end of two months the patient was discharged relieved of all symptoms. The eruption, ascites, edema, heart murmur, etc., had all disappeared, and the urine remained permanently free from albumen. The complete restoration of the kidneys argues for the fact of their having been in healthy condition before the onset of the specific infection.

Deutsche medizinische Wochenschrift, January 19 *and* 26, 1905.

The Dangers of the Common Communion Cup.—Roepke and Huss have made an extensive series of experiments to determine how great the danger of the transmission of disease germs through the agency of the communion cup really is. Sterile cups of the usual type, and containing sterilized wine were drunk from in succession by several healthy persons, and then by individuals known to have tuberculosis. The recommendations of the Imperial Health Commission to the effect that the cup shall be turned before presenting it to a fresh communicant, and that its rim shall frequently be rubbed off with a clean cloth, were carried out, but of the ten rabbits inoculated with the material obtained by wiping the lip marks with sterile gauze, eight died of tuberculosis. Not only was the rim of the cup capable of conveying infection even after rubbing with a clean cloth, but it was found that the wine itself also became infected, so that the presentation to each person of a fresh spot on the rim would not insure security. The only solution of the problem which is practical is for each communicant to have his own cup, while the church should have a suitable supply of individual cups for those who come without them, and out of deference to those who have conscientious scruples, the older form might still be retained for the use of persons preferring it.

The Diagnosis and Treatment of Renal Tuberculosis.—Casper reviews the various diagnostic measures at our command for the detection of renal tuberculosis, and says that he considers positive results after guinea pig inoculation the most important aid in recognizing the existence of the disease, and that catheterization of the ureters is essential to the determination of the side on which it is located, and of the condition of the other kidney. The statistics of five surgeons operating before the introduction of ureteral catheterization, and of five others who employed the measure, serve to emphasize the value of the procedure. Without ureteral catheterization 129 nephrectomies are reported with a mortality of 21.7%; with ureteral catheterization 130 nephrectomies with a mortality of 10%. As the operative technique has been practically unchanged during the last five years, the better results must be due to the improvement in diagnosis. This is still more plainly shown by the fact that of the deaths under the old school 22.7% were due to insufficiency of the remaining organ, while the later operators lost only 7.7% from this cause.

The Exhaustion Diseases of the Nervous System.—Edinger at the termination of a series of papers on this subject summarizes his views as follows. All of the diseases of the nervous system may be classified as focal affections, toxic affections, and exhaustion affections.. The normal exhaustion of the nervous system is demonstrable by morphological changes, and when the process is carried too far, or is not compensated for by repair, destriction of cells and fibers follows. Conditions in which this occurs the author terms exhaustion diseases, and he says that they may arise in the following three ways: (1) Through excessive demands on the normal functions and normal repair; types are occupation atrophies and neuritises. (2) Through insufficient compensation for normal function, nearly always caused by some poison such as lead, syphilis, etc. According to the nature of the poison, the exhaustion has different forms. Types are: Polyneuritis, tabes, combined systemic diseases, paralysis. (3) Through innate inability of the separate tracts to withstand the demands of the normal functions. Types are, the hereditary nervous disorders, most combined scleroses, spastic paraplegia, amyotrophic diseases in the medulla and cord, etc. In types one and two, either one or several tracts may be successively or simultaneously diseased, tabes being one of the commonest instances of such combinations. This conception is important both for prophylaxis and treatment. Since the author has allowed his tabetics to walk very little, and to perform only such exercises as are not fatiguing, and directed them to urinate every hour, to wear smoked glasses in the sunshine, and to dread all exertion, the general improvement has been very marked, and the same principles are to be applied to neuritises, palsies, etc.

French and Italian Journals.

Physiological Effects of Ovariotomy in the Goat, Especially on the Milk.—P. Oceanu and A. Babes have performed ovariotomy on the goat in order to note the effects of this operation on the elements composing the milk, on the fattening of the animal, on the prolongation of the lacteal secretion, and on the disagreeable taste and hircin odor of goat's milk. The operation was practised on the goat as on the sow, through the flank, and not through the vagina, on account of the narrowness of the vulva and vaginal canal. The advantages of the operation are as follows: The hircin odor of the milk disappears, ovariotomy being a means more simple, less costly, and more rapid in its effects than selection, and attaining the same result. The duration of the period of lactation is increased—from thirteen to fifteen months in the animals operated upon. The animal's fat increases and the flesh becomes superior to the original, without the disagreeable taste and without the hircin odor. The amount of milk given is increased. The physiological constituents of the milk are advantageously modified, in that the quantity of butter, of casein and of phosphoric acid is increased, while the amount of lactose is diminished.—*Le Bulletin Médical,* January 25, 1905.

Recent Observations in Relation to General Paralysis.—Guilly has studied in detail the etiology of aortitis which a large number of general paralytics and tabetics exhibit. He offers the following conclusions: In the course of tabes, aortitis is frequent. It is, with myocarditis and cardiac sclerosis, the cardiac lesion which is encountered in ataxic patients. Aortitis, like tabes, may be of syphilitic origin; it may be syphilitic aortitis, either acute or chronic, or it may be hereditary syphilitic aortitis. Specific treatment has a curative action on acute aortitis and on its subsequent attacks, as it has on tertiary phenomena in general. It has less effect on chronic aortitis. The treatment has no effect on the dystrophies consecutive to hereditary syphilis. In the course of general paralysis, aortitis is frequent, being found once in about five cases. Aortitis, as seen by the writer, has developed for the most part in young general paralytics, or at least in those under 45 years of age. It is, therefore, difficult to attribute these lesions to the advanced age of the patient. In the absence of any other appreciable cause, it seems to the writer permissible to refer to syphilis as the cause.—*Revue Française de Médecine et de Chirurgie,* January 23, 1905

A Fatal Case of Amebic Dysentery.—Albu observed this unusual case. The patient lived in Berlin, and was a man of 22 years. He had never been out of Europe. While on a trip to Silesia he contracted, in an unknown maner, a severe case of dysentery which proved rebellious to all treatment and which ended in his death after six months of suffering. At every microscopical examination of the stools there were found, and always in considerable numbers, amebæ characteristic of the dysentery of the tropics. In the last weeks of the illness these amebæ completely disappeared. At autopsy, ulcers were discovered involving the mucosa of the large intestine, extending from the anus to the valve of Bauhin. These lesions were not limited to the mucosa, but were found here and there in the muscular layer, although not having caused complete perforation.—*La Presse Médicale,* January 14, 1905.

Book Reviews.

BEING DONE GOOD. Comments on the Advance Made by Medical Science During the Past 5,500 Years, in the Treatment of Rheumatism. By EDWARD B. LENT, with a Foreword by CHARLES M. SKINNER. Second Edition. Brooklyn-New York: The Brooklyn Eagle Press, 1[illegible]

THIS is a humorous, and yet, beneath the surface, a truly pathetic, account of the author's search for health and deliverance from the pangs and disabling fetters of chronic rheumatism. He begins with the regular physician, and carries his readers through the baths of all kinds—electric, Turkish, and natural mineral water—the plaster cast of the orthopedist, the fathomless idiocy of the Christian Scientist, the manipulations of the osteopath, the dilutions of the homeopath, the visions of the clairvoyant, the teas of the herbalist, and the magnetic fluid of the natural healer. He tried ointments and blisters, electricity and cataphoresis, stomach washing and liver medicines, the advice of friends and the wisdom of the consulting physician, and then sat down—or, rather, sat up in bed—to tell of his experience. He sees the humor of it all, and brings this out in his narrative, ignoring the pain and the suffering; and with every right to rail at the powerlessness of medicine to relieve, and to curse therapeutic pretension, there is never a bitter word, never an unkind one. Through it all there is a lesson and an example of the patient and even cheerful bearing of one's burdens that many a less afflicted reader may well take to heart and meditate upon with profit to himself and relief to those about him. The book is one, too, that physicians may read with profit, especially when they are disposed to descant with words of pride and vain boasting upon the triumphs of the healing art. Chronic rheumatism is an old disease, probably as old as seasickness, and it seems to be just about as amenable as the latter to the therapeutic tentatives of the physician and the healer. But there is no need to drop into cynicism; we can read the book, and read it with appreciative enjoyment, as the author would have us to do.

ATLAS AND EPITOME OF OPERATIVE OPHTHALMOLOGY. By Dr. O. HAAB of ZURICH. Edited with editions by GEORGE E. DE SCHWEINITZ, M.D., Professor of Ophthalmology in the University of Pennsylvania. Philadelphia, New York, and London: W. B. Saunders & Company, 1905.

THIS new volume by Prof. Haab forms an admirable conclusion to his series of atlases on the eye beginning wit.. a discussion of the proper arrangement of operating rooms, the subject of narcosis, and the sterilization of ophthalmic instruments, the eye operations are next described with all the accuracy that the author's many years of conscientious practice on the eye warrant. The colored illustrations show with clearness of detail the most recent methods of performing the major operations. Dr. de Schweinitz, as editor of the work, has added much of practical worth and interest.

GUIDE TO THE EXAMINATION OF THE THROAT, NOSE AND EAR. For Senior Students and Junior Practitioners. By WILLIAM LAMB, M.D., C.M., Edinburgh. Honorary Surgeon, Birmingham Ear and Throat Hospital. New York: William Wood & Co., 1905.

OF introductory manuals to the study of the specialties there seems to be no end. All traverse the same ground, but as each teacher has his own point of view, so each manual has its peculiarities. The present one is simple and well executed. It follows to a certain degree, the laboratory method of teaching in that the reader is gradually carried from simple matters to those more complex and is told what he should look for and how to find it. An occasional dogmatic statement crops out, but this is to be expected under the circumstances. On the whole we regard the manual as one to be commended to those for whom it has been written.

THE ART OF CROSS-EXAMINATION. By FRANCIS L. WELLMAN of the New York Bar. With the Cross-Examinations of Important Witnesses in Some Celebrated Cases. New and Enlarged Edition. New York: The Macmillan Company; London: Macmillan & Co., Ltd., 1904.

NO doubt the accounts of operations and dissertations on painful maladies found in medical works appear sufficiently horrifying to the lay reader. The feeling must be something akin to the sensations with which one follows the present author as he details the various "methods" likely to be found serviceable to the cross-examiner in extirpating the self-possession of a witness, cauterizing his nerves, probing his past, and decorticating his inner consciousness; but the surgeon at least performs his manipulations under an anesthetic, and the sufferings he inflicts are physical, whereas it is the mind that is tortured by his brother of the gown. Still, the volume is fascinating enough, with its excerpts from the notes of famous trials to illustrate the tangled webs woven by skilful counsellors to enmesh their victims, and many a tale of the discomfiture of medical witnesses is used to point a moral and adorn the narrative.

MALIGNANT DISEASE OF THE LARNYX (Carcinoma and Sarcoma). By PHILIP DE SANTI, F.R.C.S., Surgeon to the Throat, Nose and Ear Departments, Westminster Hospital, etc. London, New York: William Wood & Co., 1905.

THIS book is an exposition of the well-known views of modern English surgeons on the matter of malignant disease of the larynx. The general attitude taken is that exploited so widely by Butlin and Semon. This portion of the work traverses only familiar ground. Statistics are here collected and some of the unusual cases on record are briefly analyzed. Particular emphasis is laid on the lymphatics of the region which, according to the author, are sharply divided into an upper area and a lower, they being separated by an intermediary zone formed by the true vocal bands, at which level the lymphatic radicles are very scanty though not wholly absent. This peculiarity explains the fact that intrinsic growths give late glandular involvement, while extrinsic growths show it early. In fact the whole matter of local spread of the disease is conditioned on the arrangement of the lymph channels. The book is interesting and accurate.

BLOOD, URINE, FECES AND MOISTURE. A Book of Tests. By [illegible] M.D. Philadelphia: George P. Pilling & Son, 1905.

THIS book of test scales consists of five circular charts colored to correspond with the percentages of hemoglobin in the blood during life and twenty-four hours after death, to standardize the colors of the urine, to show the gradations from blue to pink manifested by a disc of cobalt paper as it becomes permeated by moisture, and to form a fecal color scale. A descriptive list appended to the latter recognizes one hundred different phases of fecal coloration. The general idea and execution of the booklet are excellent, though the author's prefatory assertion that it is made to stand wear in use is not borne out by the facts, for three of the leaves of the present copy have become detached in the comparatively slight handling to which it has been subjected by the reviewer.

A PRACTICAL TREATISE ON NERVOUS EXHAUSTION (NEURASTHENIA), Its Symptoms, Nature, Sequences, Treatment. By GEORGE M. BEARD, A.M., M.D., Fellow of the New York Academy of Medicine; of the New York Academy of Sciences; Vice-President of the American Academy of Medicine, etc. Edited, with Notes and Additions, by A. D. ROCKWELL, A.M., M.D., Neurologist and Electrotherapeutist to the Flushing Hospital; Professor of Electrotherapeutics in the New York Post Graduate Medical School and Hospital, etc. Fifth Edition, Enlarged. New York: E. B. Treat & Co., 1905.

ON its first appearance this book at once received recognition as the standard treatise on the subject of nervous breakdowns, and subsequent experience has found but little to add to the original matter. The present edition differs from its predecessor in the addition of a chapter by Dr. Rockwell on the relation of the neuron theory to the conceptions of neurasthenia. While it is not unlikely that the neuron theory, as it now stands, will before long undergo more or less radical modification, as the works of Apathy, Nissl, and others seem to foreshadow, it is instructive to see the clinical and theoretical aspects of the subject correlated, and this Dr. Rockwell has accomplished in adequate fashion.

A MANUAL OF PERSONAL HYGIENE. Proper Living upon a Physiologic Basis. By American Authors. Edited by WALTER L. PYLE, A.M., M.D., Assistant Surgeon to the Wills Eye Hospital, Philadelphia; Secretary of the Section on Ophthalmology, American Medical Association; Associate Member of the American Ophthalmological Society; Fellow of the College of Physicians of Philadelphia, etc. Contributors: D. H. Bergey, M.D., J. W. Courtney, M.D., George Howard Fox, M.D., E. Fletcher Ingals, M.D., Walter L. Pyle, M.D., B. Alexander Randall, M.D., G. N. Stewart, M.D. (Edinburgh), Charles G. Stockton, M.D. Second Edition, Revised and Enlarged. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

THE appearance of the second edition of this work now only a short time after the first, is evidence that it has fulfilled the aim with which it was written. The book is made up of eight sections, each written by a prominent American physician upon his chosen specialty. In this volume new and fully illustrated chapters are presented on Domestic Hygiene and on Home Gymnastics, as well as an Appendix containing methods of Hydrotherapy, Thermotherapy, Mechanotherapy, and First Aid suggestions in medical and surgical accidents and emergencies. This manual is written with a simplicity, conciseness, and authority that make it invaluable for all interested in personal hygiene.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, Held January 17, 1905

DR. CHARLES H. LEWIS, CHAIRMAN.

Report of Case of Muscular Insufficiency of the Heart, with Gross and Microscopical Findings.—Dr. BOND STOW reported this case to show the error in physical diagnosis, comparing it with the post-mortem diagnosis. The patient was a man aged 61, a laborer, who weighed 245 pounds. He had used whiskey in large amounts for the past fifteen years and chewed tobacco in considerable quantities. He denied any venereal history except gonorrhea. His general health up to recently had been excellent. During the past four years he had had varicose ulcers on each leg. One year ago he had an attack of polyarthritis rheumatica, with apparently good recovery. Three weeks ago a cake of ice fell and crushed three of his fingers, for which he sought hospital aid. Ten days after entering hospital he noticed that he had some dyspnea, particularly upon lying down. He had also a short hacking cough, worse at night whenever he attempted to assume the reclining position. On November 9 his legs began to swell and his scrotum became edematous, but the edema soon disappeared. He complained of palpitation of the heart, headache, dizziness, and diarrhea. He expectorated a white, frothy, transparent, mucous sputum. The patient was a bright and intelligent man, with powerfully developed muscles; his skin and mucous membranes were cyanotic. He assumed the half sitting, half reclining posture, favoring the right side. There was edema of the eyelids, the scrotum, and the lower extremities. There was a venous pulse in the neck. The chest was barrel shaped. The lower right and left side anteriorly appeared to be distended, with the intercostal spaces well filled out. The respiration was rapid and labored, of abdominal type. The upper half of both right and left chests anteriorly was hyperresonant as far down as the third interspace. Vocal fremitus was increased in the upper half of both chests. In the lower half anteriorly and posteriorly it was lost. Mucous rales were heard over both sides and at the sixth interspace in the axillary line, immediately above the line of extreme dullness, was heard distinct amphoric breathing. The apex beat was in the sixth interspace, 1.5 cm. to the left of the mammary line and fully three fingers in breadth. The area of dulness, on the left side, was relative at the upper margin of third rib, absolute in the third interspace; on the right side, relative 2.5 cm. to right of right sternal line as high as third interspace, absolute 1.5 cm. to right of right sternal line. Epigastric pulsation was well marked. At the apex there was a loud presystolic systolic murmur, that at times was distinctly solely presystolic in character. The pulmonic sound was very strongly accentuated. Over the fifth interspace on the right sternal line could be heard a distinct systolic murmur. There was pulsation to be felt in the second interspace at the left sternal line, and also absolute dulness on percussion at this point. No distinct thrill could be felt at the apex, but at the third interspace one could be felt which appeared to be presystolic. Liver venous pulsation could be readily made out. The abdomen was moderately distended with fluid. The urinary analysis showed the presence of a passive congestion of the kidney. The diagnosis made was mitral insufficiency and stenosis, probably dating from his attack of polyarthritis rheumatica of a year ago, which caused an endocarditis that involved the mitral valve in usual fibrous changes found in endocarditis of rheumatic origin. Also relative insufficiency of tricuspid with passive congestion of the internal organs, fatty degeneration of the heart muscle with failing compensation causing edema of the lower extremities, etc. The post-mortem examination was made on November 23. The chest was found to contain about 800 c.c. of a pale transparent fluid in the left pleural cavity and about 1,000 c.c. in the right. There were no evidences of any pleuritis. The visceral and epicardial layers of the pericardium were united by young tender fibrinous bands that readily admitted being torn apart, evidence of a very recent pericarditis. Both ventricles were soft and flabby, and filled with a dark bluish non-coagulable blood and appeared to be dilated to their fullest extent. Upon opening the heart there were no evidences of any endocardial changes whatever. All valves appeared to be normal in structure. The weight of the heart was one pound ten ounces. The heart muscle was of a pale light brownish color. The papillary muscles showed streaks of yellow. Both lungs showed extreme congestion and edema, but there were no other evidences of pathological changes. The spleen was one-half larger than normal, weighing eight ounces. The liver weighed four pounds and three ounces and was of firm consistency. The blood vessels were deeply congested. The post-mortem diagnosis was fatty degeneration of the heart muscle with resulting muscular insufficiency of bicuspid and tricuspid valves, with subsequent cyanotic induration of the internal organs. The immediate cause of death was edema of the lungs and brain, in consequence of failing compensation of heart lesion. The particular interest in this case lay in the comparison of the diagnosis with the post-mortem one, where it was proven that the endocardium was entirely free of any inflammatory change.

Four Cases of Exophthalmic Goitre in One Family.—Dr. JOHN J. COTTER presented clinical reports of these four cases occurring in one family. The father was to-day sound and well at the age of 60 years. The mother had a "full neck" and died at the age of 42 years from valvular heart disease.

The first case was in a girl aged 12 years, the youngest of the family, in whom nothing was noted until July, 1904, when she appeared paler than normal. The child was found to be anemic, with a slight fulness in the thyroid region on both sides. The pulse ranged from 86 to 100 and was regular. There was no exophthalmos. A tonic was ordered and the child had been in apparently good health ever since.

The second patient was a woman aged 28 years, first observed in February, 1904. She complained of frontal headaches, tired easily, but complained of no cardiac symptoms. She had a very palpable increase in the size of the thyroid, more on the right side. The pulse was 99 and of good quality. Tonic measures and rest were instituted, but without effect except for a lesser degree of the anemia.

The third was a young woman, 19 years old when first observed. On exertion she had fluttering of the heart and dyspnea. Her color was fair. There was no exophthalmos or interference with vision. There was some tremor of the hands. The thyroid gland was moderately enlarged and firmer than normal. The pulse was rapid, from 100 to 120, was soft and compressible. The heart was hypertrophied and displaced to the left, with apex beat diffused. Since September, 1902, she had been under continuous observation and various combinations of arsenic, iron, belladonna, and strophanthus seemed at times to affect the heart's action favorably, but there was no freedom from the pain in the lower abdomen or along the vertebral column. In October she went to the Island of Guernsey for a change of environment, and there had been reported some general improvement.

The fourth patient was a lad aged 17 years, a clerk, first seen in December, 1902. He had been ill for some time. Sore throat was the only thing complained of. Both tonsils were greatly hypertrophied and the pharyngeal wall was studded with many islands of lymphatic tissue. The thyroid gland was enlarged bilaterally, the neck measuring fifteen inches at the greatest circumference. There was no exophthalmos. The pulse was 120. The heart was hypertrophied, the apex beat was diffused, the sounds were accentuated, but there were no murmurs. The tonsils were excised and a diagnosis of status lymphaticus suggested itself

then. An interval of almost two years passed before he again presented himself. On February 6, 1904, the goitre was very prominent and the neck measured fifteen and three-quarters inches. There was dyspnea on moderate exertion. His sleep was much disturbed by coughing. His pulse was from 120 to 135 and irregular. On March 23, 1904, the patient had lost much flesh and strength and the anemia was very pronounced. Very severe dyspnea manifested itself upon the least exertion. Excision of the thyroid was performed, it having been decided that this offered the best hope for improvement. The patient did not regain consciousness and died suddenly ten hours after operation.

Dr. William H. Thomson believed that the surgical treatment of exophthalmic goitre would soon be abandoned, and that the whole condition was due to an intestinal toxemia and did not depend on lesions of the thyroid gland.

Dr. L. Pierce Clark presented a photograph of exophthalmic goitre with unilateral exophthalmos and referred to his experience with operative cases seen at the Vanderbilt Clinic.

Dr. William B. Noyes spoke of a patient with exophthalmic goitre which had been treated by him in the Demilt Dispensary, and who had died on the table during an operation for the removal of the cervical sympathetic ganglia.

The Treatment of High Blood Pressure.—Dr. George B. Wallace read this paper. By blood pressure was meant the pressure under which the blood was circulating through the arteries, reaching a maximum with the ventricular systole, equivalent in normal adults of from 90 to 145 mm. of mercury, and a minimum with diastole, which was about 30 mm. lower than the systolic. The average systolic pressure was about 120 mm., the diastolic about 90 mm. He then considered a number of different factors which entered into the maintenance of this normal pressure. The output of blood from the heart, other factors being unchanged, must be fairly constant, and this depended upon the strength of the individual contractions and the rate at which the heart was beating. Secondly, the degree of constriction or relaxation of the peripheral blood-vessels was an important factor in regulating blood pressure. Thirdly, the volume of circulating blood had a definite relationship to the blood pressure. These various physiological factors did not act independently of each other, but a condition of equilibrium existed in a normal individual; if this equilibrium was partially or completely lost, then the condition would become decidedly pathological.

Among the different pathological conditions giving rise to hypertension were found some which exerted a rather temporary effect, which passed off as soon as proper treatment removed the exciting cause, and in this category would be included decidedly nervous temperaments, the excessive use of tobacco, and Graves' disease. The fault here seemed to be due to some disturbances of the nervous mechanism, either a lack of equilibrium between vagus inhibition and sympathetic stimulation, or a condition of increased irritability of the vasomotor center. Another condition which might be termed a temporary one was angina pectoris. The high blood pressure was due to a reflex set up by the anginal pain. The fatal result was explained as follows: The nerves of the heart were in a very irritable and hypersensitive state. Some slight cause, acting suddenly, increased their irritability, and the typical cardiac pain appeared; reflexly, an arterial spasm occurred and, finally, the heart failed through inability to cope with the greatly increased peripheral resistance. The pathological state most responsible for, or at least most generally accompanied by, high blood pressure, was arterial sclerosis. A cardiac hypertrophy was a regular accompaniment, almost always confined to the left ventricle. It would seem, however, that no special relationship existed between general arterial sclerosis and cardiac hypertrophy and hypertension. In spite of the high blood pressure existing in this condition the various organs of the body might receive much less blood than normally; thus, the cerebral symptoms so frequently complained of in arterial sclerosis were to be explained not as due to cerebral congestion, but to cerebral anemia, the heart and other organs being similarly affected. The chief object of treatment of the hypertension of arterial sclerosis was to relieve the heart of the great resistance against which it had to contend and yet to keep up a sufficient circulation through the capillaries. In connection with arterial sclerosis he mentioned atheroma, or more particularly the arterial calcification which was so frequently a sequel to it. The areas of calcification were not general, but more or less localized; therefore, what was said concerning the treatment of arterial sclerosis would apply here.

Amyl nitrite gave the most relief during attacks of angina pectoris, although in some cases it was powerless, undoubtedly because the vasomotor action was much more powerful than the muscular depression; if such was the case then the administration of vasomotor depressants, such as morphine, or chloroform inhalations, might reverse the condition and the nitrite muscular relaxation would occur. Frequently the heart had undergone an excessive hypertrophy and, in such cases, tincture of aconite would be beneficial. Again, in cases with pronounced nervousness, potassium iodide might work wonders. Cardiac malnutrition was frequently a factor and here digitalis, or better, strophanthus, would cause improvement. The nitrites should be used as well, and it should be remembered that a single dose of digitalis would act for three hours or more, while the action of nitroglycerin was usually over within an hour, and that of sodium nitrite in one and a half hours. Erythrol tetranitrate was better than the others because its action was about as lasting as that of digitalis. In the treatment of arterial sclerosis it should be remembered that the heart as a rule was hypertrophied, and therefore it needed no treatment addressed to it. Cardiac stimulants often did harm. It was a vascular relaxation which was desired and he said it was fortunate that the blood-vessels were never so diseased as to be non-relaxable. The nitrites did the most good in these cases. Glonoin could be used for years with no untoward results and no establishment of a tolerance. Glonoin, 1-50th of a grain, three times a day, was often sufficient to remove symptoms, but it was very questionable in cases where the pressure was in the neighborhood of 250 mm. of mercury whether this dosage would have as good an effect in prolonging life as would a larger dose. The iodides seemed occasionally to have the effect of giving relief in that they removed apparently some of the pathological changes responsible for high pressure.

Calcareous degeneration in connection with arterial sclerosis should, as a rule, be treated as a general sclerosis, but in addition the condition of the heart required special treatment. Cardiac stimulants were indicated, but should be used with caution, since that organ had but little reserve force and might easily become exhausted if stimulated too freely. Strophanthus would be a better drug to use in these cases, since its effect on the blood-vessels was so much less marked. In the hypertrophies of interstitial nephritis the vascular condition was strictly analogous to that of arterial sclerosis, and the treatment would, therefore, be identical. In the treatment of uremia such drugs as chloroform, chloral, and morphine were frequently of greater service than were the nitrites, since in addition to the lowering of the tension the nervous symptoms were also lessened. Care should be used, however, since these drugs were heart depressants. They were probably better used in all cases in combination with the nitrites than alone. In chronic lead poisoning with its accompanying high tension, a combination of morphine and atropine usually afblood-vessels were localized so that the blood pressure but by stopping the intense intestinal contraction. Amyl nitrite frequently brought about the same end, since it acted on other unstriped muscle than those in the vessels

it probably accomplished its purpose here primarily by relieving the intestinal spasm. Chronic lead poisoning, with continuous high pressure, came under the head of arterial sclerosis and interstitial nephritis.

Dr. Egbert Le Fevre believed that the arterial sclerosis in these conditions were localized, *i. e.* the changes in the blood-vessels were localized so that the blood pressure in different parts was unequal. If there was congestion of the abdominal vessels there was sent more blood to the brain, and that explained the tendency to rupture of the cerebral vessels. He believed that the use of nitroglycerin in these conditions often did more harm than good.

Dr. William H. Thomson criticized the reader of the paper for not having mentioned the cause of high blood pressure, the excess of secretion from the suprarenal gland, and he pointed out the relationship between kidney disease, especially when accompanied by high blood pressure, and the adrenals. In certain types of kidney disease microscopical changes could be detected in the adrenals.

Dr. Henry P. Loomis said that in using the Riva-Rocci apparatus for estimating blood pressure he had never detected any fall in the blood pressure after using nitroglycerin and the prevalent idea concerning this agent in its action in lowering the blood pressure was handed down from the older textbooks. During the past five or six years no experimental work had been done to show this. In his experience small doses of chloral were most beneficial as tension reducers, a fact which he said Dr. Wallace neglected to speak of in his paper.

Dr. Wallace said that while an excess of suprarenal secretion would cause high blood pressure, the fact that high blood pressure existed did not prove that there was any excess of suprarenal secretion. In fact, there was no proof whatever of this. With regard to chloral as a tension reducer the danger of its habitual use would contraindicate it for this purpose. With regard to nitroglycerin he believed that preparations of it must have deteriorated in activity. In one case he referred to in his paper one-eighth of a grain of nitroglycerin caused a fall of from 214 mm. of mercury to under 60 mm.

NEW YORK NEUROLOGICAL SOCIETY.

Regular Meeting, Held January 3, 1905.

Dr. J. Arthur Booth, President, *pro tem.*

A Case of Graves' Disease in a Child.—Dr. J. Arthur Booth presented a girl 13 years old, whose family history was negative. Her parents were both healthy, and there was no history of any degenerative disease in either branch of the family. The child had suffered from measles, whooping cough, and scarlet fever in infancy. She had never had a convulsion. There was no history of fright, nor could any other etiological factor be discovered. Eighteen months ago—that is, when the child was 11 years old—the exophthalmus was first noticed. Six months later the enlargement of the thyroid became noticeable, and during the past year all her symptoms had become more aggravated. The exophthalmus and thyroid enlargement were very marked, as well as the tachycardia, the pulse ranging between 120 and 140 per minute. In addition to these symptoms, there was tremor, general nervousness, sweating and insomnia, also occasional headaches. Dr. Booth said the interesting feature of the case was the early age at which the disease had manifested itself. It was usually observed between the 15th and the 25th or 30th year. There were four other children in this patient's family, who were all enjoying good health.

Adenoma of the Pineal Gland, Occluding the Aqueduct of Sylvius, with Escape of Cerebrospinal Fluid Through the Nose and Perforation of the Frontal Horn of the Right Lateral Ventricle.—Dr. Adolf Meyer presented this patient, a man who, in 1894, when diving, struck the top of his head. Following this, he complained of headache. He became blind in 1898, with chiasma symptoms. In 1899 he had transitory attacks of numbness on the left side of the face, leaving out part of the area of the middle branch. From that time there was difficulty in moving the lower jaw towards the left. There was no atrophy of the masseter. In August, 1900, cerebrospinal fluid began to drip from the right nostril, with considerable relief of the general symptoms; on the few occasions when the flow stopped the patient would become sleepy and stuporous for two or three days. During May and October, 1902, the patient, who was then 22 years old, had several general convulsions. It was during that year that he was presented by Dr. Meyer at one of the meetings of the New York Neurological Society. In January, 1904, death occured in a status epilepticus. The only permanent symptoms had been weakness of the left side of the jaw, a small area of loss of pain sensation of the lower corner of the mouth, and subjective numbness in the left side of the tongue. The gait remained normal; the knee jerks were both increased; there was no clonus. At the autopsy a tumor was found in the form of an adenoma of the pineal gland. It had pressed itself through the roof of the mid-brain, behind the posterior commissure, protruding into the third and fourth ventricle and displacing the posterior corpora quadrigemina; the adenoma had practically no sand and but slight pigmentation. The right lateral ventricle had a funnel-shaped depression in the anterior end, with a perforation through the cortex. In the case reported by Wollenberg (*Arch. f. Psychiatrie und Nervenkrankheiten*, 31, p. 206) there was a tumor of the occipital lobes, but there was no occlusion of the ventricle to help account for the perforation. In connection with the case reported by Dr. Meyer, photographs made by Dr. C. I. Lambert were presented, and Dr. C. B. Dunlap demonstrated some microscopic sections.

Dr. Meyer, in reply to a question, said the only motor symptoms the patient presented were those of the masticatory segment, which showed in the deviation of the jaw to the right whenever the mouth was opened. In other words, there was a weakness of the left pterygoid muscles. It was impossible to demonstrate any atrophy of the masseters. There were no motor symptoms referable to the upper extremities.

Old Fracture-Dislocation of the Spine, with Paralysis, Followed by Recovery.—Dr. J. Ramsay Hunt presented a patient, a laborer 45 years old. Twenty years ago he had a venereal sore, followed by a suppurating bubo. He received internal medication for one month. No secondary symptoms were noted. He has had numerous attacks of gonorrhea, followed by the development of strictures. At present a stricture of small caliber existed in the membranous portion of the urethra. In 1895 he met with a severe accident, falling three stories through an air-shaft. He was unconscious for a few minutes, and was taken to Bellevue Hospital in an ambulance. Following the accident he complained of severe pains in the back, and both legs were paralyzed, although not completely, as he could move them slightly in the bed. It was necessary to catheterize him a few times after the injury, but this difficulty soon passed away. After the accident, an angular deformity of the spine was noted, which still exists. It was located about the level of the twelfth dorsal vertebra, and it was safe to assume that the spine had suffered a fracture-dislocation at that point, and that the spinal cord had been injured at the same time. After remaining in bed for two months the legs began to improve. This improvement continued, and six or seven months later he was able to resume his occupation as a truck-driver, a laborious one, which necessitated the lifting of heavy weights. One year after the injury he was able to do a full day's work and was suffering no pain nor inconvenience. He admitted, however, that his legs were not quite as limber nor as strong as they were before the accident. He could not run as fast as formerly, owing to a slight stiffness in the knees. There were no sensory nor vesical symptoms during this period. For four years or more the patient remained in this condition. He drove a truck and led the vigorous outdoor life of a laboring man. About three years ago

there developed, very gradually, symptoms of trouble in the lower extremities. He began to complain of sensations of numbness and cold in the feet and legs, accompanied by stiffness and weakness. Upon stooping he felt a numbness in the lower portion of the back, extending down the posterior thighs and legs. During the past two years these symptoms had progressed slowly and steadily, without any sudden exacerbation and without acute pain. The left leg was weaker than the right, and it was important that this was true of the initial paralysis and the long period of disability during convalescence. At present the patient's condition was as follows: He had a well-marked kyphosis, the tip of which corresponded to the twelfth dorsal vertebra. Corresponding to this there was a posterior bilateral band of hyperesthesia at the same level. The spinal column was fairly mobile and was not tender to direct pressure or on jarring. There has been no change in the degree of the kyphosis since the accident. There was spastic paraplegia of the lower extremities, with the spasticity and clonus more marked on the left side. Babinsky's phenomenon was present on both sides. The skin reflexes were present and there were distinct objective sensory disturbances in the lower extremities, including touch, pain, and temperature, more pronounced on the right side. The man was able to stand fairly well with his eyes closed. He had considerable difficulty in urination, with occasional incontinence. He also complained of sharp, painful sensations and prickling down the posterior aspect of the thighs and legs, and on stooping he felt numb from the hips down. His sexual power was apparently unaffected. Coarse myokymic twitchings were present in the back below the level of the lesion, also in the buttocks, thighs and legs, especially their posterior aspect, after exertion and exposure to the cold. Occasionally during the past year he had sharp, shooting pains in the course of the sciatic nerves, causing reflex movements in the l[illegible] these were more pronounced on the left side.

Fracture-Dislocation of the Spine, Causing a Unilateral or Partial Lesion of the Cord.—Dr. J. Ramsay Hunt presented this patient, an elevator-operator 22 years old, who about two months ago fell six stories with his elevator. He was unconscious fifteen minutes after the fall. He was removed to the Gouverneur Hospital, where it was found that he had suffered a fracture-dislocation of the spine, the deformity corresponding to the eleventh and twelfth dorsal and the first and second lumbar vertebræ. In addition there was a fracture of the internal and external malleoli of the left ankle joint. The case was seen by Dr. Hunt six weeks later, through the courtesy of Dr. John Rogers. At that time there was an oval area of anesthesia to touch, pain, and temperature over the anterior and lateral surfaces of the right thigh. The right knee jerk was absent; the right Achilles jerk was present and not exaggerated. The left leg was weak and spastic, with clonus. The Babinsky reflex was not elicitable on either side. A girdle sensation was felt in the lower abdominal region, especially on the right side. There was difficulty on urination. Dr. Hunt said the case was a good example of a unilateral or partial lesion of the cord, resulting from a fracture-dislocation of the vertebræ. The interesting features of the first case were the recovery from the initial paralysis, the long interval of comparative normal function, during which period a laborious occupation was practiced, and then the gradual reappearance of cord symptoms referable to the same level of the cord. The progression of the disease had been most insidious, but always steadily advancing, and of such a nature as to suggest a very gradual compression of the spinal cord. It seemed reasonable to infer in such a case that the cord was undergoing gradual compression in the spinal canal, already narrowed by the fracture-dislocation and produced by an osseous outgrowth (chronic proliferating osteitis) plus pachymeningeal thickening and adhesions. Spinal syphilis or chronic inflammatory changes within the cord could be excluded. Dr. Hunt believed that surgical measures should be taken to relieve the compression.

Dr. Joseph Fraenkel said it was rather difficult to decide the exact nature of the lesion in Case I, shown by Dr. Hunt. Pressure on the cord, due to an osseous lesion, he thought, would give rise to more severe symptoms than were present in the case, and he suggested the possibility of a post-traumatic hematomyelia.

Dr. Booth agreed with Dr. Fraenkel that an exostosis would probably give rise to more pain.

Dr. Hunt, in closing, said that in studying the case the possibility of a post-traumatic syringomyelia had been considered, as well as syphilis, or a chronic inflammatory condition of the cord, originating at the site of the old injury. The theory that the symptoms followed a hematomyelia, he thought, could be discarded, from the fact that such a lesion was generally found in the gray matter of the cord, and that it would have given rise to dissociate sensory symptoms. In the first case shown it is true there were coarse myokymic twitchings, but no atrophies and no dissociate sensory symptoms. The symptoms were those of a gradual compression of the cord. In cases where the compression was of insidious onset, sharp pains were often absent. In the case shown there were pains of sufficient severity to suggest involvement of the posterior roots. The differential diagnosis was important in cases of this character, Dr. Hunt said, because of the treatment. The symptoms were growing progressively worse, and if they were the result of compression, osseous or otherwise, the advisability of an exploratory operation was worthy of consideration. This would be decided, the speaker said, on further observation and after an *x*-ray picture had been taken.

Diffuse Cauliflower-like Puckering of the Cortex in Arteriosclerotic Epilepsy, or Diffuse Cortical Cirrhosis.—Dr. Adolf Meyer demonstrated a brain that he had obtained through the courtesy of Dr. M. C. Ashley, of the Middletown State Hospital. The specimen showed a form of vascular affection, principally of the cortical terminals, in a patient 55 years old. This patient gave a history of having had syphilis at the age of 20. There was mental deterioration, with epilepsy, for 12 years, and slowly progressive left hemiplegia during the last year of life. The small vessels of the pia in the affected regions were diffusely occluded. The lesions affected principally the occipital lobes; the temporal and parietofrontal regions were also affected, leaving, however, intact the convolutions bordering on the Sylvian fossa. The case belonged to a group of which Dr. Meyer had described two instances in the Pathological Report of the Illinois Eastern Hospital for the Insane, at Kankakee, in 1896. The condition was frequently called diffuse sclerosis, but presented a distinct variety of a progressive disorder of middle life or senescence, akin to the cases reported by Pozzi, Hess, Prout, Blackburn, and, probably, also by Greiff. The term cirrhosis was used instead of sclerosis, because the latter referred more to the broader lesions taking in the white substance, whereas cirrhosis, as applied to the kidney and liver, directed the attention more to the parenchymatous portions, and in this case to the cortex itself.

Dr. T. P. Prout said that in one case he had observed where the early history was obtained it was found that it belonged to the realm of infantile cerebral palsies, upon which epilepsy was subsequently ingrafted. This was the light, the speaker said, in which he had during recent years come to regard these cases. The epilepsy was ingrafted upon an early cerebral palsy, in the same way as we saw it ingrafted upon other brain lesions.

Dr. Fraenkel said he had seen quite a number of cases in which the epileptiform seizures developed late in life, accompanied by some mental deterioration. The diagnosis was of importance, because in a younger person such a condition would be regarded as a general paresis. It was interesting to study the onset of these seizures, which could usually be differentiated from those of ordinary epilepsy by the slight focal symptoms.

Dr. Meyer, in closing, said he did not think it was justifiable to assume an infantile lesion in these cases, because it was possible to demonstrate all degrees of more

recent and older foci, with numerous granule cells. In reply to the suggestion made by one of the speakers to call these cases pseudoparalysis, Dr. Meyer said this would be apt to involve them in the general confusion of that term, which for a while stood for the cases of general paralysis on a demonstrable syphilitic basis, but which we had since learned to recognize as the backbone of that disease.

The following officers were elected for the ensuing year: *President,* Dr. Joseph Fraenkel; *First Vice-President,* Dr. J. Arthur Booth; *Second Vice-President,* Dr. Smith Ely Jelliffe; *Recording Secretary,* Dr. J. Ramsay Hunt; *Treasurer,* Dr. G. M. Hammond; *Corresponding Secretary,* Dr F. K. Hallock.

Chicago Surgical Society.

At a meeting held January 16, 1905, Dr. D. N. Eisendrath presented a case of "Stricture of the Esophagus." The patient began to have difficulty in swallowing, with regurgitation of food, about one year ago, necessitating eventually a gastrostomy. This operation was done in New York, with apparently a good result. An esophageal bougie could not be passed beyond the level of the junction of the manubrium with the gladiolus. He had the patient swallow a large amount of bismuth, and then made a radiograph, which showed the obstruction, and to the left of it a tumor. The obstruction was a sacculated one. After the passage of steel sounds the man was able to swallow milk, but at present was feeding himself through the gastrostomy wound. This case showed the value of the *x*-ray and bismuth, in the author's opinion, for diagnosing these conditions.

Dr. William Hessert presented a young woman, aged 15, with "Actinomycosis of the Jaw." The patient gave a history of toothache and a swelling of the right jaw for several months. A decayed tooth was visible, and the trouble seemed to be a necrosis of the jaw, with cellulitis in the surrounding tissue. Operation failed to disclose pus. There was a hard, indurated mass, the bone being denuded. The wound healed, but the tumor increased in size. Later, small areas of softening appeared, three or four of which were excised, and in the discharge the ray fungus was found. The patient was put on large doses of iodide of potassium and had improved steadily. The mass had diminished in size about one-half, and she could now open her mouth better than ever before. He also reported a case of metastatic renal abscesses.

In the general discussion on these cases, Dr. A. E. Halstead thought that the tumor which showed in the radiograph of Dr. Eisendrath's case probably was a diverticulum, although it might be an aneurysm. He did not think skiagraphing these diverticuli with bismuth was as good as passing a soft rubber tube filled with shot and then skiagraphing. Dr. Eisendrath said he had extirpated a kidney about five years ago for ascending pyelonephritis with multiple abscesses, and later doubted whether he did not make a mistake in so doing. Fortunately, the patient recovered without further symptoms. Dr. A. H. Ferguson referred to a case he reported some years ago of multiple abscesses of the right kidney, where he excised some of the abscesses and opened others. The other kidney became involved two years later, but the patient refused operation and died from sepsis. Dr. W. M. Harsha spoke of two cases of actinomycosis he had seen in the past year, saying that the tissue around the broken-down masses was very hard, almost gristly. This condition was marked that he considered it a valuable diagnostic sign. Dr. D. A. K. Steele favored conservative treatment in multiple embolic abscesses. Nephrectomy, however, should be the rule in tuberculous cases. Dr. Eisendrath had failed to find any evidence of aneurysm or tumor in his case after repeated examinations, and he was unable to differentiate at present between aneurysm, tumor, and diverticulum.

Dr. John E. Owens reported an interesting case of "Cerebral Tumor," removed in two stages by the osteoplastic method, with subsequent wiring of the bone flap, and the introduction of a gold plate. The primary result was excellent. Dr. A. E. Halstead and Dr. Charles P. Clark reported jointly a case of "Hydrocele in the Female." Dr. L. L. McArthur reported a case that gave a history of "Calculi in the Common Duct and Biliary Passages." One hundred and forty stones were removed. The patient died from sepsis on the third day after the operation. On section of the liver, stones were found in all the biliary ducts.

Dr. Eisendrath exhibited a specimen which illustrated the mechanism of rotary dislocations of the atlas upon the axis. He also showed an *x*-ray picture of the pelvis and both femora, in which the head of the left femur was seen to be entirely destroyed through the presence of a metastatic growth from a primary tumor of an undescended testis.

Chicago Medical Society.

At the February meeting of this Society, Dr. Joseph L. Miller read a paper entitled "Chloride Retention in Nephritis." A review of the literature since Widal and Javal's original communication showed quite uniform confirmation of their views, that patients with acute and chronic parenchymatous nephritis have marked inability to eliminate chlorides. As a result of the retention, the patient increases in weight, due to edema. The albumin in the urine, following the ingestion of 10 grams of sodium chloride daily was increased, and the patient might develop symptoms resembling uremia. In animals with artificial nephritis the use of salt increased the albumin. The organs of patients with nephritis showed excessive sodium chloride. Kovesi had shown that nephritics after the ingestion of large amounts of NaCl did not perspire, due to increased osmotic pressure of the blood, and the edema was the result of this retained fluid. As it had been shown that ingestion of large amounts of salt might increase the edema due to portal obstruction or cardiac insufficiency, and even inflammatory edema, many believed the chloride retention might be of extrarenal origin. The author had studied two cases of acute and seven of chronic parenchymatous nephritis. The chlorides were estimated by the Salkowski-Volhard method for nine consecutive days. For three days in the middle of this period the patients received, in addition to their food, 10 grams of sodium chloride daily. All showed a retention of 10 to 25 grams during the three days. The edema became more marked, the patients gained in weight, and the amount of albumin increased. Two patients showed uremic symptoms following the extra sodium chloride. Four normal individuals were examined in the same manner, and all showed a chloride retention equal to the nephritis. They also gained in weight. From this it was concluded that these patients developed an undetectable edema, while in the nephritics with the tissues already waterlogged, a moderate increase in edema could be detected. These patients did not show any albuminuria or uremic symptoms. As a final conclusion upon this matter, there was no doubt that the sodium chloride should be restricted in nephritis. The broths and soups contained a very large amount of salt. That furnished the patients in Cook County Hospital contained 11.3 grams per litre. Subcutaneous injections of salt solution must be used with caution, if at all. Dr. H. T. Ricketts read a paper on "Present Limitations in Serum-therapy." The author stated that the therapeutic value of diphtheria antitoxin was well established. No results of value had been obtained by bactericidal serums in the treatment of established infections, as, for instance, by antityphoid serum, anticholera serum, or antiplague serum. Antistreptococcic and pneumococcic serum had proven of very little value. The chief value of tetanus antitoxin was as a prophylactic, as it had been clearly demonstrated that if it was given to a patient in whom there was any suspicion or likelihood of tetanus

developing, the disease did not develop. Dr. Paul C. Freer, Superintendent of Laboratories of the Philippine Islands, spoke on plague and the late cholera epidemic in the Philippine Islands. He detailed the measures which were taken to limit the spread of these diseases. Whenever plague was suspected to exist in a certain house, a member of the laboratory staff was called in for diagnosis, and if the case proved to be plague, the patient was taken to the hospital, or, if he died, his body to the morgue, and a radical alteration of the house undertaken, either its destruction by fire, if beyond repair, or complete rebuilding, thorough disinfection, etc. The question of prophylaxis and the use of serums having become a serious one, a serum laboratory had been established there. In this laboratory were now made all of the antitoxins and sera necessary for [illegible] in the tropics, including rinderpest serum. The Boar[illegible] larged its disinfecting corps, and had perfected district organization, so that now they were enabled to cope [illegible] any epidemic of either plague or cholera efficiently.

[illegible]

At a stated meeting, held January 25, Dr. John B. [illegible]erts presented a group of specimens illustrating the [illegible] of early intervention in surgical diseases of the abdomen. One was a specimen of perforative appendicitis, in which death had resulted in consequence of delay in operation. Two were specimens of gall-stones that could have been successfully removed at an early period in their history, but that, neglected, were responsible for a fatal termination, notwithstanding surgical intervention. One was a specimen of perforation of the duodenum in which operation was deferred from a desire to reach a correct diagnosis, the fatal result taking place in the interval. One was a specimen of obstruction of the sigmoid flexure in a case in which jejunostomy was performed for the relief of a supposed obstruction at the pyloric orifice of the stomach. Dr. Roberts pointed out that often it is wise to operate when the indications for operation are present, although the exact nature of the condition demanding operation [illegible] not be clear.

Dr. H. C. Masland demonstrated "A New Saw Especially Adapted for Cranial Surgery." The instrument [illegible] a circular saw mounted in a strong, rigid handle, having a cutting edge of only 1 mm. in width, and operated by electric power. Only rectilinear incisions were possible, but these could be made in an exceedingly brief time and with great safety. The instrument was separable and capable of perfect sterilization.

Dr. B. C. Hirst presented a communication entitled "The Limitations and Possibilities of Electricity in the Treatment of the Diseases of Women." He commended warmly the employment of galvanism and faradism in the treatment of some cases of uterine fibroids, uterine hemorrhage, atony of the myometrium, and lack of development of the internal generative organs.

Dr. T. H. Weisenburg read a paper entitled "The Toxic Changes in Brain and Spinal Cord Due to Carcinoma." He pointed out that, in addition to metastasis to the nervous system and its coverings, symptoms of disease of this [illegible]m are not rarely observed in cases of malignant disease. He reported the finding of degenerative changes in the cells of the brain and cord, sometimes even independently of recognized clinical phenomena. The symptoms are sometimes transitory, and they may give rise to confusion by simulating organic disease.

At a stated meeting held February 8 a symposium was held on the subject of "Gastric Ulcer." Dr. Joseph McFarland discussed the Etiology and Pathology, taking up for consideration questions of age, sex, occupation, incidence, number, and situation, and rehearsing the various theories that have been proposed to explain the occurrence of the lesion. He was inclined to accept the view that the underlying cause is a loss in local resistance or of immunity in consequence of circulatory conditions influenced perhaps by nervous conditions." Dr. A. P. Francine presented a communication on "The Incidence of Gastric Ulcer in Philadelphia, with Special Reference to the Post-mortem Records of the Philadelphia Hospital." He had found that the total number of medical admissions to the Philadelphia Hospital between the years 1893 and 1902, inclusive, was 39,542, the total number of autopsies 2,830, and the total number of cases of gastric ulcer 38, of duodenal ulcer 2, and of gastric and duodenal ulcer 2. These figures showed, in conjunction with others from other sources, that both clinically and pathologically gastric ulcer was less frequent in the United States than in London and on the continent of Europe, and likewise more common in the northeastern than in the more southern portions of the United States, with the exception of San Francisco. Particular importance was attached to nephritis and tuberculosis as etiological factors in the development of gastric ulcer. Dr. Campbell [illegible]. Howard of Baltimore read by invitation a paper on the "Symptomatology and Diagnosis of Gastric Ulcer." He dwelt upon the cardinal symptoms of pain, vomiting, and hematemesis, and considered also the derangements of gastric function, the changes in the blood, and the impairment of nutrition, special attention being directed to the presence of blood in the stools. He pointed out the difficulties in diagnosis, and referred to a number of conditions from which ulcer of the stomach was to be differentiated. Dr. F. P. Henry read a paper on the "Medical Treatment of Gastric Ulcer." He dwelt on the necessity for rest, both general and local. The former was to be secured by recumbency in bed, the latter by rectal feeding. The disease must be considered a medical one in the absence of alarming hemorrhage or of perforation. Dr. W. L. Rodman read a paper on the "Surgical Treatment of Gastric Ulcer." He took the ground that surgical intervention was justified only when medical means had failed after a fair trial. The treatment would vary somewhat, as the ulcer was acute or chronic. In the one instance the indication for treatment would be found in the occurrence of copious or dangerous hemorrhage, and in the danger of perforation, and the treatment would consist in excision and suture. In the second instance, while the indications were essentially the same, the treatment would vary somewhat in accordance with the conditions present. In a given case excision and suture might be required, in another dilatation of the pylorus, in a third gastroenterostomy.

Northern Medical Association of Philadelphia.

At a stated meeting, held January 27, Dr. Augustus A. Eshner read a paper on "Epilepsy." He defined this affection as a paroxysmal neurosis, characterized by attacks attended with derangement of consciousness or of motor coordination, with or without convulsions. The factors underlying the epileptic paroxysm were considered as consisting in the action of some irritating influence upon an unduly irritable or unstable sensorimotor mechanism. The irritant might be chemical (introduced from without or generated within the body), or mechanical (vascular or circulatory, foreign bodies, extravasations, products of inflammatory, hyperplsaitc, or neoplastic processes). The morbid irritability or instability might be inherited or acquired. Four types of epilepsy were considered briefly, viz., major, minor, focal, and psychic. The indications for treatment comprise the removal of irritating influences and the correction of abnormal irritability or instability. Each case must be studied by itself and be treated individually. The entire mode of living should be adjusted and regularity and moderation in all activities insisted upon. Excitement, overtaxation, and fatigue should be avoided. The diet should be simple, digestible, nutritious, and unstimulating. The patient should eat slowly and masticate thoroughly. The use of tea, coffee, alcohol, tobacco, and meat should be interdicted. Outdoor

exercise and sufficient sleep should be secured. The functions of all organs should be maintained in as high a state of perfection as possible. Opportunity should be afforded for healthful and agreeable occupation, and this can be best attained through the colony method of care and treatment. To avoid accident the patient should be left alone as little as possible. Therapeutically, effort should be directed to breaking up the convulsive habit. For this purpose the bromides in varying doses and combination constitute the most reliable remedy. Antipyrin is a useful adjunct, and so also, especially in cases of petit mal, is digitalis. Sodium borate in doses of 5 or 10 grains thrice daily has proved a satisfactory alternate with the bromides. Mere change in treatment or in the attending physician sometimes has a good effect.

Surgical Suggestions.

Amputation Suggestions.—Murphy [illegible] hints on amputations of the lower extremity. Where [illegible] posterior muscle flaps when obtainable are to be preferred to the circular cuff of skin. The fibula should be cut off at a higher level than the tibia in leg amputations, and care should be taken to bevel off bony prominences such as the sharp anterior tibial edge. Suture of the periosteum and approximation of the muscles and fasciæ are desirable. Drainage of the stump is advised, unless the dead space is obliterated by means of buried sutures. Partial amputations of the foot or amputations at the ankle-joint, except under unusual conditions, are not as satisfactory as those above the ankle-joint. Tibial stumps between six and eight inches long are the most serviceable. Amputations through the knee-joint are inferior to those just above the condyles. The longer the thigh stump the better, provided the condyles have been removed. In general, in tibial amputations down to four inches and in thigh amputations down to five inches, sacrifice bone in order to obtain good muscle flaps.—*Harvard Medical Bulletin.*

Phlebitis.—Tavel treats phlebitis of the saphenous vein by ligating it above the inflamed portion in order to prevent embolism.

Prosthetic Paraffin Injections.—Stolz says that this method of repairing defects should be used with great caution in gynecological practice. It is only in exceptional cases that it is to be recommended in cases of uterine or vaginal prolapse, and then only when operation must be avoided, pessary treatment is inadequate, and subsequent pregnancy need not be feared. The greatest care should be taken to gain the assurance that the point of the needle is not within a vein, and it is best to inject only small quantities at each sitting. At subsequent sessions the injection should always be made into the center of the already present mass in order to diminish the risk of embolism. The prolapse should be corrected before the injection, and a pessary be worn for twenty-four hours afterward, or the vagina be packed. Rest in bed should follow the injection. The question as to whether vaselin or hard paraffin is preferable in these cases is still undecided, but, theoretically at least, paraffin seems most suitable.—*Monatschrift für Geburtshülfe und Gynäkologie.*

Treatment of Tuberculous Ascites.—Schumann reports excellent results in these cases following the aspiration of the fluid through a trocar of moderate size, through which iodoform emulsion is then injected into the peritoneal cavity. The emulsion is made in a strength of from one to five parts of iodoform to one hundred of glycerin. The first injection is of 1-2 c.c. of the 1 per cent. solution and the amount and concentration are increased according to the progress of the case. The injections are repeated at intervals of from four to eight days. The author considers the method in every respect preferable to treatment by laparotomy.—*Centralblatt für Chirurgie.*

Diagnostic Value of Leucocytosis.—McCaskey says that a single leucocyte count is entirely insufficient as a basis of conclusion in any given case, and should be followed up by several others made under different conditions. In the diagnosis of malignant disease a leucocytosis is of very subordinate value, and when present is probably not due to the malignant disease *per se* but to coexisting chemotactic toxins.—*American Journal of the Medical Sciences.*

Paraphimosis.—When chancroid or a mixed sore is the cause of, or complicates, paraphimosis, the sore, as well as the incision, should be at once cauterized with carbolic acid crystals. Neglect promptly to reduce paraphimosis may result in gangrene of the parts in front of the constricting band, with all the coincident dangers to the organ and to life itself.—Prendergast, in *Memphis Medical Monthly.*

Books Received.

While the Medical Record *is glad to receive publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 18, 1905:

	Cases.	Deaths.
Measles	209	8
Diphtheria and Croup	272	47
Scarlet Fever	225	20
Smallpox	1	1
Chickenpox	132	.
Tuberculosis	339	171
Typhoid Fever	23	4
Cerebrospinal Meningitis	.	40
Typhus Fever	.	.
Yellow Fever	.	.
Cholera	.	.
Totals	1,201	291

Hebotomy (Extra-Median Symphyseotomy).—Th. H. Van De Velde in citing one of the cases in which he has performed hebotomy, gives the following description of the operation: The patient was placed in the gynecological position, but with the legs not strongly flexed. A compress closed off the vulva entirely. The bladder, which was lying on the left side, was catheterized. The skin was incised almost two fingers' breadth to the right of the median line, beginning at the upper border of the os pubis, running somewhat inwards and downwards through the outer side of the labium majus to below the border of the pubic bone. There was very little bleeding. The index finger of the left hand pushed the fat aside in the lower angle of the wound and was pressed [illegible] bone, where it remained, and guided the needle which was introduced by the right hand and was easily passed around the os pubis. The point emerged from behind through the muscular attachments on the upper border, whereupon the left hand, no longer having to support the needle below, pressed the tissue against it from above. As the needle became visible in the upper angle of the wound the wire saw of Gigli was hooked into it, the instrument was withdrawn, keeping the saw moderately tense, the needle was turned into a handle for the saw by a simple manipulation, and the bone was sawed through in a few strokes. The patient had a generally narrowed, flat, rachitic pelvis, and the child was large. When the wound had been covered with a gauze compress, the child was extracted, the head being drawn through the pelvic entrance very easily. After the birth of the second child, for it was a twin pregnancy, the vulva was again entirely covered with a compress, and, after renewed disinfection of the hand, the hebotomy wound was closed with a continuous silk suture. A small rubber drain was laid in the lower angle of the wound. On about the eighth day the sawed ends of the bone were bound together by an evident callus. All tenderness had disappeared. The writer designed a permanent enlargement of the pelvis, which was obtained in a very simple manner. In this respect, as well as in every other, the writer thinks that hebotomy is far superior to symphyseotomy. This enlargement is not obtained at the expense of the solidity of the pelvis. As to the side to be sawed through, it should be decided on which side it is to be expected that the parietal eminences will pass through. For on that side the opening in the pelvic ring should be made. The presence of varices or hernia or an evident situation of the bladder on one side will be an indication for making the incision on the other side. In spontaneous or artificial breech positions, hebotomy should be performed on the side on which the back of the child lies, and the anterior foot should be brought down. If it is preferable to saw through on the other side, extraction should be performed by the posterior leg. When anesthesia is formally contraindicated, the operation can very well be performed without it. The spreading apart of the sawed surfaces seems to be slightly or not at all painful. The writer does not omit drainage in general. The cutaneous incision should be in the labium majus, as far outward as possible, but the cut through the bone should not be too far from the median line. Hemorrhage should be checked at once. After the separation, a large gauze pad should be pressed firmly on the wound. The patient should be laid on a hard mattress after the operation, with a cloth smeared with unguentum camphoræ under the sacrum. It is unnecessary to use an immobilizing bandage. The writer considers hebotomy an ideal operation.—*Annals of Gynecology and Pediatry.*

Japanese Army Ration.—The Japanese soldier does his fighting on a diet consisting largely of rice and dried fish. According to a correspondent of *London Truth*, the rice is cooked in the following way: It is boiled until quite thick and glutinous. Next it is placed on a ceramic slab, rolled out and cut into squares. The squares are then placed in the sun to dry and often turned. When hard as sea biscuit and greatly reduced in weight they can be stored. A certain number are allowed each day to the soldier. All he has to do is to break up a square in boiling water and to add the dried fish. In a few minutes he has what seems to him a delicious thick soup. If he cannot procure boiling water, he simply eats his rice cake dry. In the fruit season he substitutes fruit, when he can obtain it, for the fish.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended February 17, 1905:

THE DIGESTION OF CASEINS, AND ITS RELATION TO CERTAIN PROBLEMS IN INFANT FEEDING.*

BY THOMAS S. SOUTHWORTH, M.D.,

NEW YORK.

ATTENDING PHYSICIAN NURSERY AND CHILDS HOSPITAL, NEW YORK CITY CHILDREN'S HOSPITALS AND SCHOOLS, PHYSICIAN OUT PATIENT DEPARTMENT BABIES' HOSPITAL.

DESPITE the steady advances which have been effected during the last decade in the technique of the artificial feeding of young infants, and a vastly clearer understanding of the indications calling for definite changes in the percentages of fat and proteids in modifications of cow's milk to meet definite clinical symptoms, no commensurate progress has been made until very recently in elucidating the complex problems of digestion. In the absence of such progress all methods of infant feeding have rested chiefly upon empirical bases. This has been largely due to the fact that Hammarsten's conclusions of twenty-eight years ago concerning the precipitation of casein in the presence of acids were stated by him with such positiveness that they have since been accepted and copied without question by writers upon this subject. Fortunately, however, the spirit of modern commercialism which leads to the yearly appropriation of thousands of dollars of public moneys for the investigation of methods of improved feeding and caring for domestic animals by which they and their marketable products shall bring increased wealth to the nation, has through the study of able scientists solved this problem which also has so important a bearing upon the welfare of the modern human infant.

Van Slyke and Hart, in their studies of the production of cheddar and cottage cheeses, established the fact that both organic and inorganic acids have a definite action upon calcium casein, the form in which casein exists in combination with calcium in fresh cow's milk, and upon calcium paracasein, the clot produced by the action of rennet on fresh milk, forming first free casein and free paracasein and then compounds of casein and paracasein with the acids. They also undertook experiments to discover the relative digestibility of these compounds. Their discoveries published in the bulletins of the New York Agricultural Experiment Station at Geneva, N. Y., and in the American Chemical Journal, have not thus far found their way generally into our text-books, nor has any attempt been made to apply the important principles involved fully and clearly to the physiology of infant feeding. To make these plain to the general practitioner is the purpose of this article. This new light which is extremely interesting and suggestive to the pediatrician, while establishing upon a firm basis many views which have been arrived at by the long and tedious processes of clinical observation and experimentation, will at the same time call for a recasting of much of our accepted teaching.

The milks of all species of mammals have certain characteristics in common in that they all contain fat, sugar, proteids, mineral salts and water. Of these, the fat and sugar may be said roughly to be the heat and energy producing elements, which keep the young alive and furnish the motive power to the body, while proteid, which alone contains nitrogen, is the constructive element which builds the body, making blood, repairing waste, and forming new cells in growth.

The proteids of milk are divisible into casein and a group of soluble albuminous bodies. These latter, the soluble albuminous bodies, are not precipitated, as is casein, during digestion, but remain in the fluid which separates from the casein curd, and are readily absorbed by the digestive tract. The quantity of proteid or nitrogenous bodies contained in the milk of different species varies very decidedly. This amount of cell-forming, tissue-building material, varies in direct proportion to the rapidity with which the young of the species grow and the length of the period after birth in which they mature and become independent of the mother's mammary glands for nutrition, being greater in those which require it for rapid development. But this is not all, for the physical characteristics of the casein curd formed during digestion bears a definite relation to the type of digestive organs peculiar to the species as seen in the familiar examples of the fine flocculent curds of breast milk in the infant's stomach and the solid and more massive curding of cow's milk in the stomach of the calf whose digestive apparatus is to be fitted to deal with coarse bulky food. This diversity in the physical characteristics of the casein curd formed in the milk of different species forces upon us the conclusion, not as yet absolutely proven, that there are probably certain differences in the caseins of the various milks, and it must be clearly borne in mind that when we speak of the caseins of milks we are speaking of dissimilar bodies which react to rennet, acids, or the digestive juices in very different ways. One of the great obstacles to a proper understanding of this subject in the past has lain in the fact that the caseins of all milks were supposed to be alike. It is now definitely accepted that the caseins of different milks are not interchangeable with equal digestibility for the stomachs of the young of different species.

* Read at a meeting of the Pediatric Section of the New York Academy of Medicine, February 9, 1905.

With the kind permission and coöperation of Prof. L. L. Van Slyke, the nomenclature of the casein compounds has been changed in the text of this paper, subsequent to its reading at the Academy of Medicine, in order to conform to his advanced work upon this subject, which is about to be published.

Casein as it exists in milk is called calcium casein. The rennet clot of milk is called calcium paracasein. The products resulting from the action of small amounts of acids upon these two bodies, formerly called mono-acid salts, are now known as free casein and free paracasein. Those resulting from the action of larger amounts of acids, formerly called di-acid salts, are now known as lactate, hydrochloride, etc., of casein and paracasein.

It has long been known that the casein of milk was precipitated in more or less solid form outside the body in the presence of rennet or by acids, and also during the process of digestion by the action of the digestive secretions. But important as the question is, our knowledge of the chemical changes which take place in casein when acted upon by acids as during digestion have until very recently been based largely upon theory owing to Hammarsten's incorrect deductions from his experiments. The discoveries of Van Slyke and Hart make it clear that acids have a definite chemical action upon calcium casein and calcium paracasein, and have furnished proof that no gastric digestion by pepsin takes place until calcium casein or calcium paracasein has been acted upon by acid and converted either into free casein or free paracasein (base-free proteids), or into their compounds with acid.

A clear conception of the processes which take place during the digestion of milk has long been needed and will now prove of the greatest aid in understanding the hitherto obscure and complex problems of infant feeding.

Immediately after the birth of the young the mammary glands secrete a fluid called colostrum which is transformed by gradual changes into that to which we give the name of milk. Colostrum is less readily coagulated than milk, and being suited for intestinal digestion passes quickly through the stomach, but in its passage doubtless has the property of awakening and stimulating the digestive secretions of the stomach.

The first secretion of the stomach of the young is the ferment rennet. The rennet ferment acts upon the calcium casein of the milk, forming a soft clot which is called calcium paracasein (junket). If no acid is present this paracasein clot may pass on into the intestine where it is readily digested by the pancreatic and intestinal secretions. The pepsin secreted by the stomach will not attack calcium paracasein in the absence of acid. But when hydrochloric acid begins to be secreted by the stomach this reacts with the calcium paracasein formed by the action of the rennet ferment, making first free paracasein and then a definite chemical compound known as hydrochloride of paracasein which is fitted for gastric digestion and is now readily attacked by pepsin, and true stomach digestion begins.

The physical character of these curds, both in size and density, varies according to the species of the mammal, and the free paracasein and hydrochloride of paracasein curds have a tendency to shrink and become more or less tough, depending upon the kind of milk. This tendency to shrink into tough curds is especially marked in cow's milk.

The digestion of the infant is in process of evolution and is not to be thought of as the same as the digestion of the adult. In the adult, gastric digestion is accomplished by the hydrochloric acid and pepsin of the gastric juice, which also disintegrates the food which leaves the mouth in particles of varying size. Digestion progresses most rapidly when free acid is present. In the young animal whose gastric function is in process of development, and who secretes at first no acid, and later but gradually increasing amounts, coarse food causes disturbances for some time after birth, until both the stomach and its secretions are developed. It is one of the most remarkable things in nature that milk which itself retains practically the same composition throughout lactation, is changed by the action upon it of the developing gastric secretions into forms and compounds which require at first moderate, and later more extended gastric digestion, by which means the stomach is progressively called upon to perform more and more work until it is sufficiently developed anatomically and physiologically for the animal to begin its subsistence upon the types of food consumed by the adult of its species.

If the stomach secretes a small amount of acid only, but little of the soft calcium paracasein clot is changed into the somewhat tougher free paracasein, through the union of the acid with the calcium. The free paracasein is readily dissolved in dilute salt solution, which suggests an explanation of the good results claimed from the addition of salt to the infant's bottle. With such moderate secretion of acid by the stomach, a part only of the calcium paracasein is therefore prepared for gastric digestion by pepsin, while the remainder of the soft unaltered calcium paracasein which cannot be attacked by pepsin, passes on into the intestine, where it undergoes digestion by the intestinal ferment trypsin and other digestive secretions. A still more abundant secretion of gastric juice, *i.e.* of hydrochloric acid plus pepsin will change more of the milk into a form suited for gastric digestion than a less abundant secretion. Thus the work performed by the stomach is normally regulated automatically.

But this is not all, for when the hydrochloric acid comes to be present in amounts greater than is necessary to form free paracasein with those parts of the calcium paracasein clot which it can readily attack, depending upon the size and density of the curds, the excess of acid unites with some exposed portions of the free paracasein in such a way as to form a definite compound, hydrochloride of paracasein. Such a salt of paracasein is more difficult to digest in the absence of uncombined acid in the stomach than free paracasein, but when there is acid enough secreted by the stomach to also give uncombined free acid, the acid compounds of paracasein are more readily digested by pepsin. These changes in the curds increase the scope and task of gastric digestion by which the developing stomach is trained to cope with more and more difficult problems in its preparation for its future task of digesting the solid food of adult life. But since the calcium paracasein clot is attacked upon its surface by acid, and curds, especially of the milks of different species, may vary much in size and density, the chemical action of the acid may penetrate them to different degrees, and it is consequently entirely possible to have at the same time within the curd or in the gastric contents, in varying proportion, paracasein hydrochloride, free paracasein, and calcium paracasein, depending either upon the admixture or contact of the acid with the stomach contents or upon the strength and quantity of the gastric secretions.

The nursing infant secures directly from the maternal breast a fresh and unchanged milk which nature has adapted to its peculiar needs and its digestive equipment. When cow's milk is substituted with its different proteids and its liability to changes of bacterial origin, certain new factors are introduced, which must be discussed in the light of our recently acquired knowledge.

Not only may the hydrochloric acid of the stomach form with paracasein definite compounds in the forms of curds such as alone occur when fresh breast milk is taken directly into the infant's stomach, but similar compounds may be formed by the combination of casein with other acids, sulphuric, acetic, etc., but notably also by lactic acid, which is the normal acid of sour milk. Since lactic acid forming bacteria are invariably present in commercial cow's milk, however carefully it is handled, the action

of the smaller or larger amount of lactic acid which they produce in the milk must be definitely reckoned with. Neither the lactic acid bacteria nor the lactic acid which they form are hurtful *per se*, in fact, lactic acid may be administered under certain conditions as a remedial agent, but the combinations resulting from the action of lactic acid with calcium paracasein may under certain circumstances interfere with normal digestion.

Lactic acid reacts with calcium casein outside the body to form first free casein (formerly called monolactate) and casein lactate (formerly called dilactate). This is the curd of sour milk or the familiar cottage cheese.

If milk which has begun to sour from the development of lactic acid, but has not yet curdled, is taken into the stomach where it meets with rennet even in the absence of hydrochloric acid secretion, the rennet ferment will attack it, forming curds which rapidly turn into tough curds of free paracasein and lactate of paracasein.

Again where milk is ingested in which the lactic acid forming bacteria have had an opportunity to multiply, even though their growth has not advanced so far as to make the milk taste sour or to cause curdling, the growth of these germs does not cease when they reach the stomach, but on the contrary, the temperature of the body is most favorable for further development, and the formation of firm masses of free paracasein and lactate of paracasein is the inevitable result.

Hydrochloric acid and pepsin are presumably secreted by the normal stomach in physiological proportions to each other. When, however, more acid is introduced from outside in the form of lactic acid, or produced under favorable conditions by lactic acid bacteria in the stomach, the total acids are disproportionate to the amount of pepsin secreted. More of the paracasein is therefore transformed by this resulting excess of acid into a form calling for gastric digestion than the stomach can care for. Unfortunately this kind of curd of which an excess is formed, and which is fitted only for gastric digestion, is unfitted for intestinal digestion, and these tough curds, like foreign bodies, may pass through the intestines causing colic or other disturbance.

It is this production of lactic acid, whose presence may increase the quantity of tough curd beyond the digestive capabilities of the stomach, which often produces a portion at least of the pernicious results when an infant's food prepared from unpasteurized or unsterilized milk is kept at room temperature or in an improperly cooled ice box, or kept warm during a part of the night so as to be ready for the infant without further trouble to the parent, or when a bottle, once used, is reheated for a subsequent feeding. In fact, whenever unpasteurized or modified milk is subjected for a considerable time to a temperature above 60° F., which allows of the multiplication of lactic acid bacteria, and an increase of lactic acid short of that which produces a visible warning by the curdling of the casein.

On the other hand, if the souring of the milk has advanced outside the body to the point of complete curdling with the formation of curds of lactate of casein (not paracasein) in a very finely divided state such as is seen in buttermilk, the rennet ferment has no action on these curds when the milk is ingested and the formation of tough acid paracasein curds is prevented. Such a compound of casein with acid is less tough and more finely divided, and therefore, to this extent at least, more digestible than the corresponding compounds of paracasein with acid. Such facts as these probably account for the dangerous qualities of turning or partly soured milk, while fully soured clabber, buttermilk, etc., are more digestible. Animal experiments have even shown that sour milk is more readily digested by adults than sweet milk. The rather surprising results claimed by Baginsky and others from the use of buttermilk as a food for infants and young children will, if substantiated by more general employment, probably be shown to rest upon a similar basis. Both Koumiss and Zoolak, which are the products of certain alcoholic fermentations of milk with the production of lactic acid, contain soft flocculi of casein in combination with lactic acid, similar to the curds of sour milk and probably owe their digestibility to the fact that these, as we have seen, cannot be transformed into tougher, larger masses by the action of the rennet in the stomach.

Lactic acid has long been advocated, especially by the French school, as a remedial measure in diarrheas of bacterial origin. This use was based upon a knowledge of its influence in repressing bacterial growth. We now recognize more exactly that the lactic acid forming bacteria prevent especially the development of the groups of putrefactive bacteria, and that this is accomplished by the lactic acid which they produce.

Since lactic acid bacteria thrive and multiply in the presence of starch and sugar, their bactericidal influence would be intensified by a carbohydrate diet, and we may find in this a rational explanation of the beneficial results in intestinal conditions, and especially in the so-called summer-diarrheas of restricting the diet temporarily to gruels, because these furnish a favorable medium for the growth of the lactic acid germs while furnishing no pabulum to the putrefactive groups.

Pasteurization has a definite although indirect influence upon the digestibility of the calcium casein of cow's milk, in that by destroying the lactic acid germs, and preventing the formation of lactic acid, it allows the hydrochloric acid of the stomach alone to form combinations with the calcium paracasein, and the free paracasein and hydrochloride of paracasein which are thus formed will more probably be in proportion to the amount of pepsin secreted.

The author has shown elsewhere that the use of alkaline antacids, limewater and bicarbonate of soda, which were introduced into food mixtures for young children in order to make acid cow's milk correspond in reaction to a supposed alkaline breast milk was based upon a fallacious theory, since the use of a more accurate indicator, phenolphthalein, has now shown breast milk also to be faintly acid. He has also shown that the use of 5 per cent. limewater and one grain sodium bicarbonate to the ounce, which is one ounce of limewater or 20 grains sodium bicarbonate to every 20 ounces of pure milk or food mixture, as advised by certain authorities, was an erroneous application of the theory to practice, inasmuch as the actual proportion of the alkali to the quantity of milk varies, of course, with the number of ounces of milk in the twenty-ounce mixture. This results in a high alkalinization of the small amount of milk used in the mixtures for young infants, and a gradually decreasing alkalinization as the mixtures are made stronger by the addition of larger quantities of milk. The true explanation of the utility of alkaline antacids must therefore be sought in some other direction and is to be found aside from certain individual effects which each alkali produces upon the milk and in the neutralization of any lactic acid formed in the milk after it is drawn, in the fact that in the presence of an alkaline reaction the rennet ferment is retarded or inhibited and clotting and curding of the milk is prevented or delayed, allowing

the escape into the intestine of part, at least, of the still fluid milk. This tends to divide the labor of digestion to a degree depending upon the amount and kind of alkaline antacid used, between the stomach and intestine and may thus avert the overtaxing of the stomach with subsequent disastrous effects upon the entire gastrointestinal canal.

Peptonization of milk is a well recognized measure for increasing the digestibility of its casein, but it is too frequently employed without knowledge of the principles involved. The term "peptonization" itself is perhaps an unfortunate one, since its root suggests to many digestion by pepsin, which can only take place in an acid medium and alone represents typical gastric digestion. This view is still encountered with great frequency among all classes. "Pancreatization" and "pancreatized milk" would have been better terms, since the preparation used for this purpose contains 5 grains of extractum pancreatis and 15 grains sodium bicarbonate. The process is therefore analogous to an intestinal digestion in an alkaline medium. Upon the length of time during which the ferment is allowed to work upon the milk before its activity is checked by heating or cooling depends the amount of the casein which is changed into a non-coagulable form, but whether much or little is transformed the alkalinity caused by the bicarbonate of soda, especially if the food has been subsequently heated, restrains the rennet and acids of the stomach to a larger or smaller degree from playing their usual part in the digestion of the remainder, and so prevents to any considerable extent, the formation with the unaltered casein of tough acid paracasein curds. In short, gastric digestion is more or less cut out and the intestine receives material upon which its own work of digestion is already more or less advanced.

With this explanation in mind, no practitioner will repeat the not very infrequent error of attempting to produce some sort of "peptonization" by adding pepsin to the child's bottle, for since commercial pepsin invariably contains the rennet ferment the result is to cause a clotting of the calcium casein in the form of calcium paracasein which is really a precipitate of "junket" or "curds and whey."

Chapin states, and any may repeat the experiment, that milk diluted with even as high as ten parts of water can be so manipulated that the curd formed by adding rennet and dilute hydrochloric acid will be all in one small piece. We have in this a demonstration that it is possible, even with very dilute milk, to have the formation in the stomach of typical solid curds, and milk approximately so diluted is not infrequently resorted to for cases of difficult digestion, especially for those in somewhat older infants. If we apply our knowledge of the reactions of casein with rennet and acids to this phenomenon of the formation of tough curds even in very dilute milk, we will see that the smaller the amount of casein in the child's food the greater will be the relative proportion to it of the hydrochloric acid secreted by the stomach. Such relative excess of acid would tend to form the tougher hydrochloride of paracasein, while if the food were made stronger, that is, if more milk within reasonable limits were added to the mixture which would increase the amount of casein, the same amount of hydrochloric acid would have the opportunity to combine with the larger amount of casein, and so tend to form the softer and more digestible curds of free paracasein. Such would be a possible explanation of the improved digestion and more normal stools which not infrequently follow a radical increase in the strength of the food where previously even very dilute mixtures have been accompanied by indigestion and curdy stools. It may also demonstrate why large quantities of dilute food may fail when smaller quantities of more concentrated food will succeed. In this connection, however, it should be stated that experiments upon the young of the lower animals show clearly that the growing stomach craves work, and increasing work, so that the continued use of highly diluted food which does not furnish a proper mechanical stimulus to the stomach may lead to deficient secretion and faulty digestion. This is remedied when a judicious increase in the strength or concentration of the food furnishes the required stimulus.

With a definite statement of the chemical changes taking place in casein when subjected during digestion to the action of the secretions and a knowledge of the factors which favor, intensify, retard or inhibit these processes an exceedingly fascinating field opens before us in the direct application of these principles to the ordinary clinical indications of infant feeding and to the elucidation of hitherto obscure questions. Take, for example, the familiar instance of the passing by an infant of firm, leathery curds in the stools. If true tough curds are passed in the stools it indicates that the milk has somehow been subjected to an excessive acidity, allowing the formation of too much tough acid curd of paracasein which the pepsin secretion has not been equal to the task of digesting and which was in a form unsuited for intestinal digestion. This may occur in several ways: (*a*) Excessive secretion of hydrochloric acid in the stomach; (*b*) milk slightly sour from formation of lactic acid before it was modified; (*c*) milk after modification kept too warm and so slightly soured from the production of lactic acid as the result of bacterial growth; (*d*) lactic acid or other acids formed in the milk after reaching the stomach, when there is tardy digestion.

In the last three cases the lactic or other acids are in addition to any hydrochloric acid secreted by the stomach. To remedy such a condition the problem requires investigation to see whether the milk was clean and fresh to start with, whether it was properly prepared and kept cool, or whether the difficulty has arisen directly from the child's digestive functions.

We may then have respectively,

To secure a fresher milk;

To see that it is kept properly cool;

To pasteurize it to kill the lactic acid forming bacteria;

To add alkalies in order to neutralize acids formed outside of the body, or present in the stomach when the milk is ingested.

To add alkalies in sufficient amount in order to prevent or to modify the action of the rennet ferment and hydrochloric acid of the stomach;

To peptonize it so that the casein can no longer form tough curds;

To use gruels to mechanically separate the curds;

To decrease the quantity of milk in the food so that no larger amount of curd is formed than the stomach is prepared to digest.

To increase the amount of milk, in rare cases, so that the type of curd shall be better suited for the individual digestion.

Each of these measures may have its special indications in certain cases. To discover the most probable cause and to choose the suitable remedies is therefore a definite but often a complicated problem.

Other problems will readily suggest themselves, and their number can probably be almost indefinitely extended, but the increased knowledge which we have acquired furnishes us with simple and intelligible explanations of many of the phenomena which have long been surrounded with mystery and neces-

sarily been dealt with empirically. We are never to lose sight of the fact that cow's milk was made for the peculiar requirements and digestion of the calf, that however modified it was not primarily intended for a human infant's stomach, and that it is a strange substance which the stomach must adapt itself to digest. When difficulty is experienced in doing this, it should be remembered by the practitioner that there is a great deal in infant feeding beside dilution of the milk and the addition of sugar. The main thing is to get the child to absorb sufficient nutriment for well rounded development, and there is more than one way of doing this. If the stomach makes a botch of digestion the intestine can often be made to do the work, but this should not be continued after the stomach is again able to perform its functions. If the intestine is incompetent, the gastric digestion must be assisted to perform its functions creditably.

Granting, as we must, that there may always be a margin of variation between the chemical combinations and reactions produced in the chemist's laboratory and those which fickle but resourceful nature produces in the body, still a sufficient amount of what we have known and what we have surmised is now established upon such a definite basis as to furnish the incentive for further investigation along these lines of the chemistry and physiology of digestion, upon which most of the advances in infant feeding must now probably be made.

807 Madison Avenue.

A STUDY OF FIFTEEN CASES OF ERYSIPELAS TREATED BY INJECTIONS OF ANTISTREPTOCOCCUS SERUM.

By J. C. AYER, M.D.,

NEW YORK

ADJUNCT-ASSISTANT SURGEON BELLEVUE HOSPITAL, CONSULTING SURGEON NASSAU COUNTY HOSPITAL, MINEOLA, N. Y.

In a previous paper[1] I have given a composite statistical description of seventy-nine typical cases of erysipelas, all of which, with the exception of four cases, were treated by the usual methods in vogue before the introduction of serum therapy. With the data thus obtained as a basis of comparison, I have made a study of fifteen similar cases which came under my care at Bellevue Hospital in the summer of 1904, all of which were treated by subcutaneous injections of streptococcus antitoxin.

Since the introduction of serum therapy in the treatment of erysipelas by Marmorek in 1895, many observations on its effects have been made both in this country and in Europe, with what seem to be definitely good results. The efficacy of the treatment in this disease, as is the case in all diseases of this class treated by similar methods, depends very largely upon the length of time which has elapsed between the onset of the disease and the beginning of the treatment. Also, the amount of serum necessary to protect or cure increases in geometrical proportion with the time elapsed since inoculation with the disease.[3]

The immediate beneficial effects of the injection of 10 c.c. to 20 c.c. of serum are often very striking, although I regret to say, not uniformly so. In favorable cases, the patient's general condition is often greatly improved at the end of a few hours. His temperature comes down with a sudden drop; the pain and burning are diminished, he becomes less restless and often falls into a quiet sleep, awakening free from many of the distressing symptoms which ordinarily accompany an acute infectious disease; so that, barring the slight weakness incidental to the febrile state, he is scarcely conscious of being ill.

A decrease in the violence of the local conditions goes hand in hand with the constitutional improvement, so that frequently within a few hours after the first injection, the swelling becomes less marked, and desquamation begins to be apparent.

As regards the condition of the urine, Marmorek[4] makes the statement that when treatment begins within a few hours of the onset of the disease, no febrile albuminuria will develop; but that if the albuminuria has already shown itself, one or two injections of serum will cause it to disappear permanently. The effect on the leucocytosis is generally quite as striking as it is on the other conditions mentioned above. From a high initial count taken before the first injection, the count at the beginning of desquamation is usually within a few hundreds of normal. Suppuration beginning after the treatment has been well established is rare, and glandular enlargements are checked and reduced. It is said that patients who are subject to recurrent attacks of erysipelas will be protected against these recurrences by an injection of 10 c.c. per week for four or five weeks.

The deleterious effects which I have observed have been so mild and of such little consequence that they scarcely require more than a passing notice. As a matter of fact, the only bad result which I have personally observed, is that sometimes, at the site of the puncture, an erythematous or papular eruption appears, but this is usually of

CONDENSED HISTORY OF THE INDIVIDUAL CASES.

Serial number	Day of disease on which treatment was begun.	Duration of disease in days.	Days of the beginning of desquamation after first dose of serum.	Number of injections. short duration, and is attended with no other symptoms worth mentioning.

In forming a judgment as to the value of one kind of treatment as compared to another, it is important that the mortality statistics of the disease

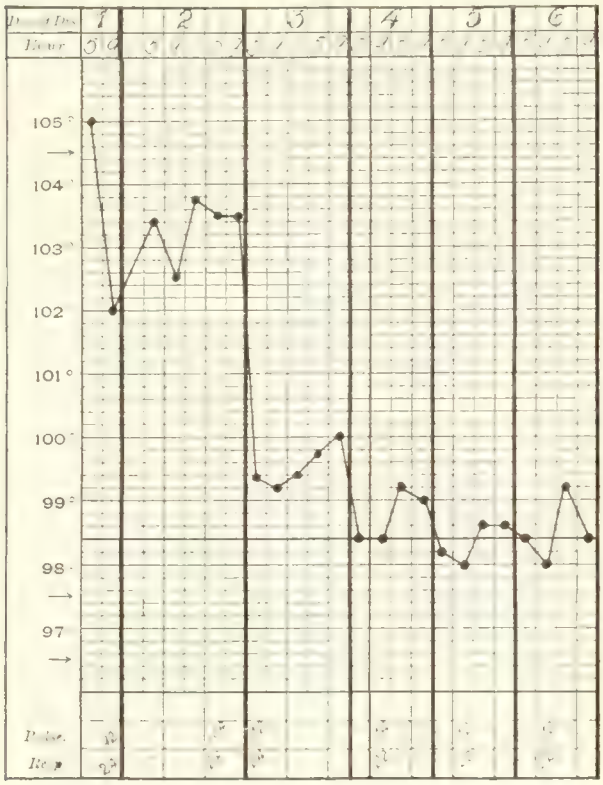

Chart of Case I.

in question should be of such a character that the exact cause of death is made perfectly clear. This requirement I do not find to be satisfactorily filled in my study of the statistics which I have at my

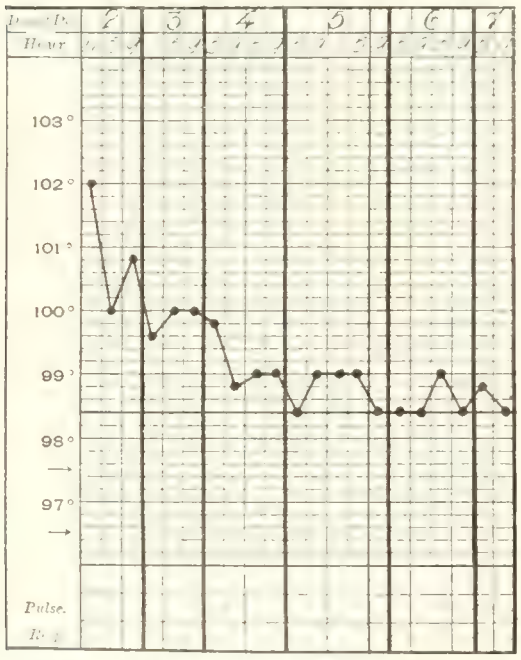

Chart of Case II.

command. For example, in the statistics given by Tison,[10] I find no mention of complications as a contributory cause of death, while in my own statistics, based on a study of seventy-nine cases, nearly all the deaths were directly traceable to complications, and not to erysipelas, *per se*. Tison gives a mortality of 3.79 per cent. in 554 cases, but says nothing about complicating conditions; whereas, in my own statistics I find a mortality of 14.75 per cent., of which only 1.25 per cent. was due to erysipelas directly, the other 13 per cent. having been caused by a complicating wet brain, delirium tremens, pneumonia, uremia, chronic nephritis and pyemia. In view, therefore, of the unsatisfactory character of the mortality statistics in judging of the value of the serum treatment as compared to the older methods, I prefer to rely rather on my observations on the general conduct of the disease, its severity, duration, etc., as compared to similar conditions observed in cases treated by the older methods.

On page 325 is a table which is designed to show at a glance the salient points observed in each of the fifteen cases under consideration, all of which

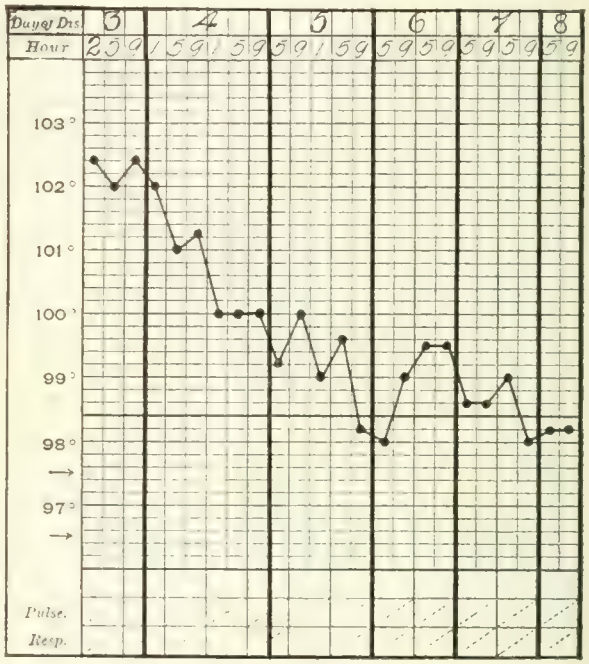

Chart of Case III.

were treated with antistreptococcus serum beginning from the time of the patients' admission to the wards. The following is a summary of the table showing the average duration of the disease with reference to the time when treatment was begun.

In order to accentuate what I consider to be a very important point, I have arranged the cases

Number of cases.	Day of Disease when Treatment was Begun.	Beginning of Desquamation after first dose of serum.	Duration of disease.
1	1st day	3d day	4 days
1	2d day	3d day	5 days
7	3d day	2d day	5 5/7 days
3	4th day	4th day	9½ days
1	5th day	1st day	9 days
1	6th day	1st day	11 days

in a sequence based upon the length of time which had elapsed between the initial symptoms of the disease, and the beginning of treatment—this latter being coincident with the time of the patient's admission to the hospital.

As my previous statistics were not based on the same data which I have used as a foundation for

the present tables, I am unable to make any direct comparison between the two. The only positive statements which I can offer, based on the two sets of statistics, relate to the headings "average duration of disease" and "mortality," and these comparisons I give here, though the disparity between the number of cases in each set is too great to make the deductions of much importance. In the seventy-nine cases treated in the old way, the average duration of the disease was 9.4 days of the fifteen cases treated by serum, it was 7.6 days. The mortality under the old form of treatment was 1.25 per cent.; under the serum treatment it was *nil*.

I give below six charts of as many patients, with each of whom the treatment was begun on a different day of the disease, ranging from the first to the sixth day. A study of the temperature curves shows a general downward tendency, beginning, as a rule, immediately after the first dose of serum, though in one case considerably delayed. The holding up of the temperature in this case was undoubtedly due to the coexistence of a profusely suppurating surgical wound of the mastoid.

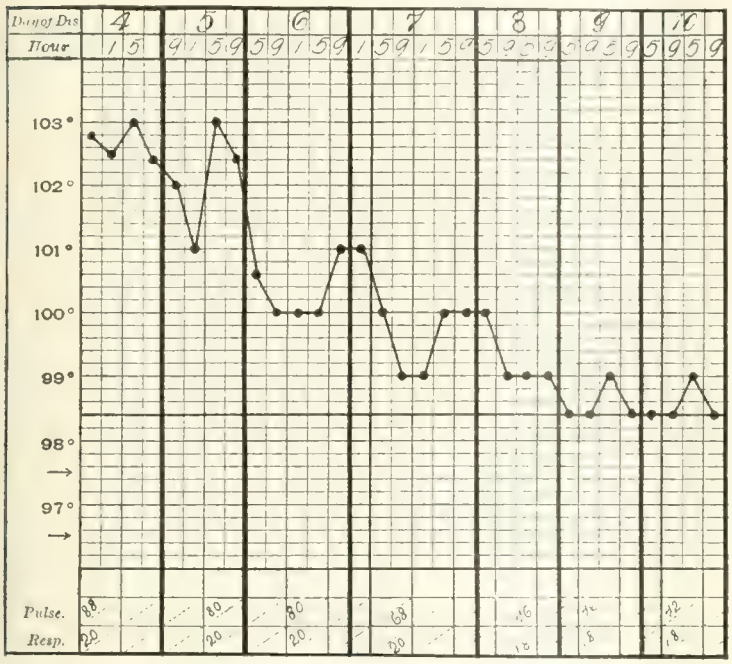

Chart of Case IV.

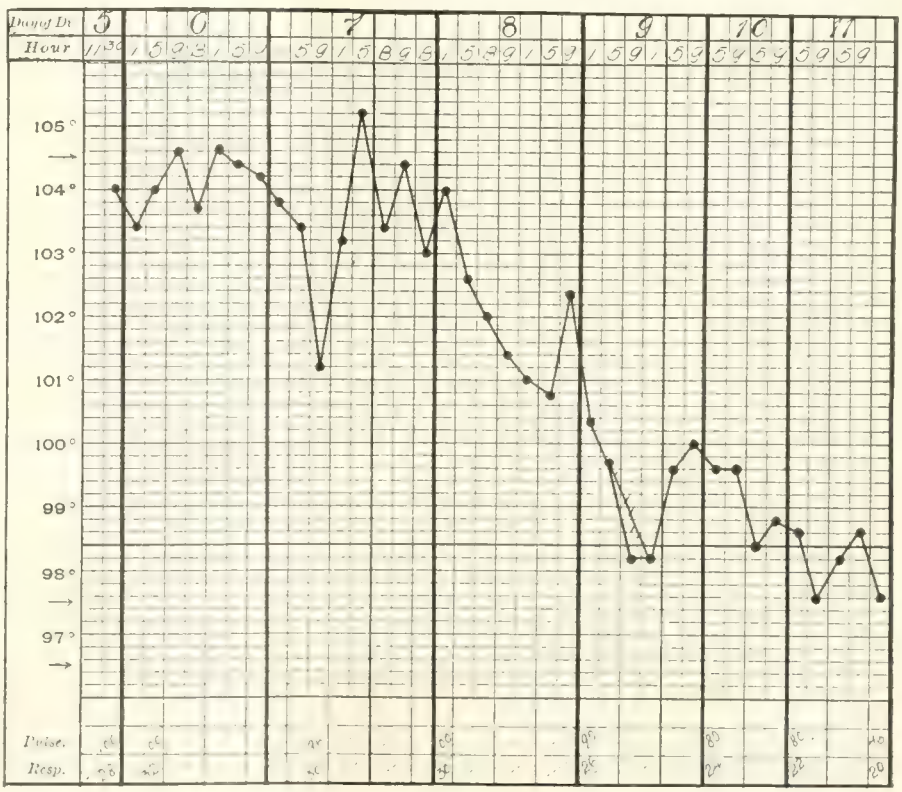
Case I.—M. F., admitted July 27, 1904. This morning at 8 o'clock the patient had a well-marked chill, and one hour later vomited. At the same time she noticed her leg and ankle were red, swollen and tender. Admitted on the first day of disease. Local signs and symptoms diminished twenty-four hours after first dose of serum. July 27: 20 c.c. serum injected at 9 P. M. July 28: 10 c.c. serum injected at 10 A. M., 2, 6 and 10 P. M.; local signs and symptoms diminished; leucocytes 17,000. July 29: Nearly all signs of local inflammation have disappeared; leucocytes 7,800. July 30: Leg normal except slight swelling around ankle. July 31: Slight tenderness around heel is all that remains of the disease. August 1: Discharged cured.

Case II.—T. M., admitted August 1, 1904. Yesterday he was attacked with chills and vomiting, and noticed that the skin about the knee was red, swollen, and tender. Admitted on second day of disease. Local signs began to disappear 14 hours after first dose of serum. August 1: 10 c.c. serum injected at 11 P. M.; patient complains of considerable pain; Leucocytes 16,600. August 2: No pain; feels well; local signs much improved; redness, swelling, and tenderness much less. August 3: Patient feels perfectly well; nearly all local signs have disappeared. August 4: All signs of acute process have disappeared; desquamation begun; patient up and about. August 5: No local signs; ready for discharge; leucocytes 8,800. August 6: Discharged cured.

Case III.—J. M., æt. 36, admitted July 14, 1904. Twelve days ago the patient had convulsion and fell, sustaining scalp wound. He was well until two days ago, when he had general malaise, and at the same time the scalp wound became painful. The next day on awaking the face was swollen and red. The man had no chill or vomiting. Admitted on the third day of disease. Desquamation began 31 hours after first dose of serum. July 14: 20 c.c. serum injected at 3 P. M. July 15: 20 c.c. serum injected at 11 A. M. and at 8 P. M.; there was slight desquamation of face. July 16: Desquamation of face and forehead marked; leucocytes 9,800.

Case IV.—H. W., æt. 18 years, admitted August 1, 1904. Three days previous to admission patient was operated upon at the Manhattan Eye and Ear Hospital for mastoiditis. The day before admission the region about the wound became



red, swollen and tender, and patient had chilly sensations. Admitted on the fourth day of the disease. He did not respond to serum until the fourth day after first dose. August 1: 10 c.c. serum injected at 2, 6, and 10 P. M.; leucocytes 42,500. August 2: 10 c.c. serum injected at 5 and 9.30 P. M.; left side more swollen than yesterday; right side becoming involved. August 3: 10 c.c. serum injected at 11 A. M., 3 and 9 P. M.; local conditions same as yesterday; no improvement. August 4: 10 c.c. serum injected at 11 A. M.; both sides of face much better than yesterday; tenderness disappearing; leucocytes 14,000. August 5: Local signs almost completely disappeared.

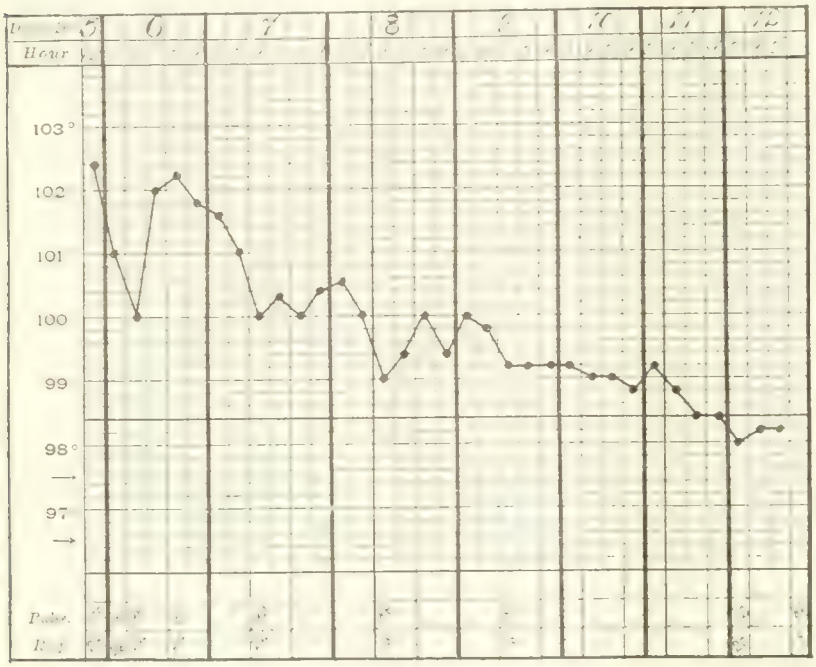


Chart of Case VI.

August 6: All local signs have disappeared. August 7: Patient up and about; retained in ward on account of mastoid wound, but the erysipelas is cured.

Case V.—L. M., admitted July 20, 1904. Five days ago the patient noticed redness, swelling, and tenderness over the bridge of the nose. The same night she had chill and vomiting. Patient admitted on fifth day of disease. Her condition was complicated by suppurating tuberculous glands of the neck, which very probably contributed to the holding up of the temperature. Desquamation began 21½ hours after the first dose of serum. July 21: 20 c.c. serum injected at 11.30 P. M. July 22: 10 c.c. serum injected at 1 P. M.; at 9 P. M. slight desquamation on nose; leucocytes 16,000. July 22: Desquamation marked this morning; 10 c.c. serum injected at 11.30 A. M., 4, 8, and 11.30 P. M. July 23: Desquamating freely on face and forehead. July 24: Local signs have disappeared. July 25: Temperature normal; condition good; allowed to sit up in chair.

Case VI.—A. E., æt. 53, admitted July 12, 1904. Five days ago the patient had severe chill and vomiting, and at the same time noticed redness and swelling at the base of the nose. On admission entire face, ears, and scalp were involved. Patient admitted on sixth day of disease. Desquamating freely 19 hours after first dose of serum. July 13: 10 c.c. serum injected at 1 A. M. July 14: 20 c.c. serum injected at 11 A. M.; at 8 P. M. he was desquamating freely.

As to the effects of the serum upon suppurating processes, my observations were not sufficiently extensive to be of any importance, though the impression gained from a very few cases was not encouraging.

The serum used, was, I am given to understand, prepared by a method similar to that which Marmorek used in making his original serum in 1895.

I am indebted to Dr. Blackwell, the House Surgeon, for the careful manner in which the records were kept from which I have made the above deductions.

Conclusions.

1. That the administration of antistreptococcus serum shortens considerably the course of uncomplicated attack of erysipelas.

2. That it tends to inhibit extension of the disease.

3. That it has a strikingly beneficial effect upon the general condition of the patient, reducing the temperature, pain and discomfort incidental to the disease.

4. That it rapidly reduces the pathological leucocytosis.

5. That it prevents or suppresses febrile albuminaria.

6. That its use is attended with no danger, even in large doses.

7. That the only disagreeable symptom referable to the serum observed by the writer is a transient eruption which occasionally occurs at the site of the injection.

8. That the efficacy of the serum treatment is in direct ratio to the length of time which has elapsed between the onset of the disease and the first injection of serum.

Antiseptic Feeding.—The chief of the Paris Laboratory in a popular lecture is reported to have said: "When a man takes milk for breakfast preserved with formic aldehyde, when he eats at luncheon a slice of ham kept good by borax, with spinach or French beans made green with sulphite of copper, and when he washes all that down with half a bottle of wine cleared with an excess of plaster of paris, and that for twenty years, how is it to be expected that such a man can have a stomach?"—*St. James Gazette.*

CHRONIC RHEUMATISM, GOUT AND OTHER URIC-ACID DIATHESES TREATED BY THE *X*-RAY, HIGH FREQUENCY CURRENTS, AND VIBRATORY MASSAGE.

By SINCLAIR TOUSEY, A.M., M.D.
NEW YORK.
SURGEON TO ST. BARTHOLOMEW'S CLINIC.

My own experience is based upon hospital as well as upon private cases, though the patients whose histories are briefly given in this paper were all treated in private practice.

The *x*-ray has been applied only locally and only in cases of palpable deposit about a joint or nerve of a nature which has been found resistant to the other applications. The *x*-ray does not form part of my "Uric Acid Technic," but has proven to be a most valuable adjunct in occasional cases. When required, the *x*-ray has been applied in the dosage indicated by the following formula:

I use an eight or twelve inch coil with primary winding to give a large amount of induction (self-induction in the primary), a Wehnelt Interrupter or an Electrolytic Interrupter of the type generally known as the Caldwell, with fine rapid interruptions —at least 10,000 a minute—a primary current of 3½ to 4 amperes. (The 110 volts direct current of the electric lighting system being cut down to this strength by the resistance of the interrupter and by a separate rheostat.) This would produce a continuous stream of sparks across a five-inch space, but is passed through an *x*-ray tube of 40 or 50 cm. rating, of the heavy anode Müeller, Gundelach or Friedlander regulating type. The most important element in the correct application of the *x*-ray for radiographic or therapeutic purposes, is the adjustment of the degree of vacuum in the tube. The quality of the light is absolutely dependent upon this. We have learned that it is as impossible to take a picture through the lumbar region with a tube in the wrong condition, as it is to read a newspaper in the dark; and my work in Röntgen therapy has taught me that success or failure here also is dependent upon technic. For these rheumatic or gouty deposits, the vacuum in the *x*-ray tube is regulated so that with the current described above, the resistance in the tube will back up a spark of three inches and the light will show clearly through three layers of tin-foil (100 square inches to the ounce) in the author's radiometer. The distance from the anode to the nearest skin surface is nine inches, the time of exposure from three to five minutes twice a week, the operator and all parts of the patient except the affected area—about five inches in diameter—are protected from the action of the *x*-ray by enveloping the tube itself in a Friedlander shield. The effect of such application of the *x*-ray is anodyne and resolvent of the deposits alluded to. But there are cases in which a thickening deformity and disability have existed for years and may prove incurable even by this means. The pain relieving quality of the *x*-ray, properly applied, is one of its most certain effects in these cases as well as in cancers and other conditions such as Rigg's disease of the gums in which it is used therapeutically. The *x*-ray is not applied in sufficient dosage in these rheumatc cases to excite any reaction in the skin, no redness or tanning or exfoliation, and it is only exceptionally that it is used at all in uric acid cases.

My "uric acid technic" consists in the application of vibratory massage over the abdomen and up and down the spine for about ten minutes twice a week and the application of high frequency currents on the same days for about fifteen minutes over the abdomen, up and down the spine and over the affected joints or nerves. The vibrator which I have used in most of these cases consists of a 1-16 horsepower motor with a flexible shaft, at the extremity of which is a hollow metal ball, within which an eccentric metal knob revolves at a very high rate of speed. The metal ball is applied in these cases, so that the effect produced is a tapping with wonderfully short quick strokes. We have to avoid the spines of the vertebræ, or other thinly covered bones, and with this precaution the application is very pleasant indeed.

The other portion of this technic consists in the application of high-frequency currents over the abdomen and up and down the spine and over the affected joints or nerves. The apparatus employed is an eight or twelve inch *x*-ray coil run by the direct 110 volt electric lighting current, either with an electrolytic interrupter, of the type described in the previous paragraph as used for the *x*-ray, or a Wehnelt interrupter in which there is a large jar containing dilute sulphuric acid in which one lead electrode rests, the other electrode terminating in a platinum point surrounded by a porcelain tube beyond which a greater or less length of the platinum point may be protruded. The greater the length exposed the less rapid are the interruptions and the heavier is the current transmitted. We use in the primary coil a current of about three and a half amperes interrupted about ten thousand times a minute. The poles of the *x*-ray coil in which a very powerful secondary current is thus excited are attached to the inner coatings of the two Leyden jars which form part of a d'Arsonal transformer. The inner coatings communicate with each other across an enclosed spark gap, and my best results have been obtained with the spark gap not much more than half an inch long. The outer coatings of the two Leyden jars are connected by a large loose coil of wire called a solenoid and another passes from the outer coat of each Leyden jar to the patient. One of these insulated wires terminates in a metal handle held by the patient and the other terminates in an insulated handle of my own device, which is held by the operator and into which screws a glass vacuum tube of suitable dome shape for application over the surface of the body.

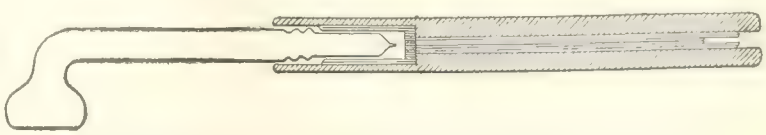

Fig. 1.—Tousey completely insulated handle for high frequency current electrode.

The handle is of heavy hard rubber, but these currents are of such high tension that it is necessary to secure further insulation from the operator's hands by having the handle hollow with the conducting wire stretched along its axis and surrounded by an air space. The whole is so constructed that no part of the metal (cords or handle) is exposed and it is impossible for operator or patient to receive any spark or current except from the glass electrodes.

This enables us to reach parts without inconvenience, which we would otherwise have to twist and turn around to treat.

In connection with this new handle and electrodes of mine (Figs. 1 and 2) the vacuum electrodes are best made with a fine wire passing through the glass at the point where the metallic contact is made

with the handle. The current would pass through the glass without this wire, but this arrangement gives a stronger current and without it the glass would become quite hot at the point of contact with the handle. In operation, the vacuum tube becomes filled with waves of violet and ultra violet light; ten thousand a minute passing down and disappearing in the tissues of the patient. A certain amount of ozone is generated, some of which is carried into the tissues and which can be detected upon the surface several hours later. In addition, a current of very high frequency and tension and of about one hundred and twenty-five milliamperes passes through the body of the patient from the metallic handle which he holds, to the glass vacuum electrode. This is a current of greater actual volume than can be comfortably administered in any other

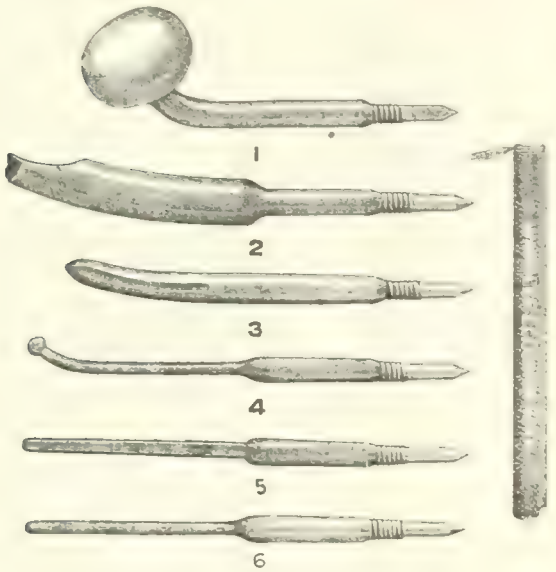

Fig. 2.—Electrodes for high frequency currents.

manner, and in this case there is no sensation at all except a gentle warmth where the vacuum electrode is in contact with the patient. This, as will be noted, is a bipolar application, but a unipolar application producing much the same effect is made by means of the Oudin resonator. This consists of a separate loose spiral of heavily insulated wire made like a flat mat, the outer and inner terminals being connected with the two poles of the d'Arsonval transformer, and the inner terminal being connected more or less directly with a vacuum electrode. Only this one wire passes to the patient and a regular brush discharge takes place if the glass electrode is separated from the surface. The self induction in this additional coil of wire renders it possible to secure much more powerful effects, even painful effects if necessary.

The immediate effects of the vibratory massage are an increase in the superficial circulation, an excitation of nerve function, and if the pressure is deep and prolonged an inhibition of nerve function and a stimulation of the blood circulation in, and the functional activity of, every viscus over which it is applied. So that it results in improvement of the functions of the liver, stomach, intestines and kidneys; and in this way it is perfectly easy to understand its usefulness in the uric acid diathesis; applied along the spine, however, the way in which it benefits is less evident; the fact that it does benefit this diathesis is something that I have verified again and again.

The immediate effect of high frequency currents over any considerable area of the body varies according to whether the glass vacuum electrode is in good contact with the skin and also whether it is moved rapidly over the surface. A good contact with the skin is facilitated by the application of some toilet powder and the current then passes into the body without sparking and with a sensation of warmth, which is greater when the electrode is moved slowly over the surface than when it is moved rapidly. With the author's technic there is practically no prickling sensation, no sensation like that from static sparks or from galvanic or faradic currents and no trace of muscular contraction like that from galvanism or faradism. There is a slight increase in the cutaneous circulation and sometimes a sense of exhilaration which used to cause one patient to feel like walking all the way home to Seabright, N. J.

Freund, in his excellent work on Radiotherapy, quotes the observations of d'Arsonval, Berlioz, Tripet, Lacaille, Denoyes, Martre, Rouvière and a great many others upon the physiological effect of high frequency currents in hundreds of cases. They go to show that an increase takes place in the amount of urine and in the amount of urea, uric acid and other solid ingredients contained therein; also an increase in the amount of oxyhemoglobin in the blood. But Freund says that these statements of d'Arsonval and his pupils have not been generally confirmed. The cases of uric acid diatheses treated by the present writer have practically all been in office practice and there has hardly been an opportunity to definitely settle either of these points. The ultimate beneficial result, however, has been demonstrable in the urine as well as in the bodily condition of the patient. I have sometimes taken a patient's temperature and found it the same before and after treatment by high frequency currents alone. Probably what takes place is a counter irritant effect upon the superficial nerves, with a reflex effect upon the blood circulation in, and functional activity of, the internal organs, and a certain added oxydizing effect from the free ozone absorbed, and an effect from the ultra violet and other rays so abundantly present.

Applied in a different way from my own very active counterirritation and even blistering or skin destruction can be produced, but these efforts are hardly desirable in the cases under consideration.

One characteristic case is that of Mr. J. P., whose history follows: Father's family in general robust and of large build. Grandfather died at fifty-nine of apoplexy, father died at thirty-nine of inflammatory rheumatism (convalescent, cold bath, relapse, heart affection), uncle died at seventy-seven of old age, another uncle died at fifty-six of "ossification of the heart," an aunt at sixty-four from "paralysis of the throat." Mother's family in general weakly, of slight and rather small build, grandfather died at seventy-nine of old age, grandmother at eighty, having suffered from liver complaint between the ages of thirty and sixty years; mother died at twenty-nine of puerperal fever, had always been delicate, aunt died at seventy, worn out always, delicate, never any disease; sister died at twenty-three, rapid decline, always delicate; brother living, strong constitution, probably weak heart, light attack of inflammatory rheumatism lasting for ten days at the age of forty-nine, but had been drinking freely.

The patient was a man aged fifty-four years, constitution inherited from mother's side; soft condition to the age of twenty-eight, never robust, torpid liver, only sickness since childhood inflammatory rheumatism; in bed thirty-nine days, temperature over 100° only five days, maximum 103.8°, heart

not affected, vaccination has always shown blood in good condition, wounds heal readily, perspires very easily and freely, always muscularly weak, maximum walk without undue fatigue *only* some sixteen miles. At age of fifty-two his doctor told him he was one in ten thousand as to general condition. His present trouble dates from two years ago when he had an attack of lumbago of a gouty order, with which he was not sick in bed, but which was very severe for ten days; any movement in the morning being very difficult, but improving through each day; the symptoms disappearing in about two months. He attributes that attack to over fatigue at business by day and social calls, with late hours, by night, lack of nutrition in boarding house diet, and constant worry over money matters. His general condition is usually good until the end of March, when he becomes played out until he has had one month's daily sea-bathing, beginning June 20th; and after three months at the seaside his condition remains excellent until the end of the following March. He leads a very simple life with strictest moderation in all things. He is a man over six feet four inches in height and weighing about one hundred and seventy-eight pounds, with the arches of both feet somewhat broken down and this gives an extraordinary breadth to the ball of the foot. The right great toe-joint is swollen and stiff, and there is a gouty pain in it, especially on wakening. The middle toe of the right foot has a sensation as of slipping out of joint. The right knee has a feeling of rheumatism. There has been so much trouble along the lines indicated as to have put him to considerable expense in the matter of medical treatment and to have threatened to incapacitate him from business. Shortly after beginning treatment he had a fall which produced a severe ecchymosis of the left thigh, followed by stiffness of the knee, the left much more than the right, and a "crick" in the left knee and an added rheumatic pain in the left hand.

The treatment consisted in the high frequency currents and vibration twice a week, according to the author's "uric acid technic," the administration of ten grains of salophen three times a day, the application of flat-foot plates, and the recommendation to avoid tea, coffee, and tobacco. At the end of a month the gouty pain in the great toe had almost disappeared, the stiffness and the crick in the knee resulting from the blow had been reduced two-thirds. The sensation as of the middle toe slipping out of joint had almost gone. Only a trace remained of the rheumatic sensation in the right hand, and the rheumatic pain in the left hand brought on by the fall had been reduced three-fourths. After another two weeks' treatment the patient reported himself so well in every way that it seemed proper to discontinue treatment.

This case with the flat-foot element combined with the uric acid diathesis is typical of a large number, both in men and women, which are hard to cure by medical treatment alone. They are always benefited by the method of applying high frequency currents and may usually be cured. There is an altogether extraordinary improvement after the first treatment and before they have had the prescription for salophen made up. It has seemed from observations on many cases as if the very first treatment brought them up to their very best level from the period of greatest pain and depression, which has finally caused them to be sent for this special treatment. There is no backsliding from this level, but for two or three weeks there is very little perceptible advance. Then as suddenly as in the first instance further improvement begins and in a month or so the average case is well.

Another case is that of Miss D., aged fifty years, referred by Dr. Cyrus Strong. She is a very large woman, weighing two hundred and eighty-seven pounds, but without any surplus adipose tissue. An aunt died of chronic rheumatism after being helpless for years, and there was a similar tendency all through the family history. She, herself, had very serious trouble with her mouth, the permanent teeth having practically no enamel, being somewhat notched and having been preserved only by many years' attention when she was a young woman. She understands that her case is a classic one in dental history. She has always been careful about diet, but has gradually become more and more affected by a rheumatic or gouty condition, which in spite of the best medicinal treatment has finally almost crippled her and she has not been able to walk more than two or three blocks, and on coming to a curbstone would hesitate for some time before attempting to step up those two or three inches. The knees were badly swollen and the joints of both feet were stiff and swollen, as was also the middle finger of the right hand.

The first treatment consisted of high frequency currents over the abdomen, knees, feet, hand and up and down the spine, and the following day she was walking any number of blocks and going up and down stairs and "feeling like a bird." This was before she had begun any medication. At the subsequent treatment vibration was applied over the abdomen and up and down the spine in addition to the vacuum electrodes as above described. The original brilliant improvement remained, but was not surpassed until about two or three weeks more of two treatments a week. Then she started in to make a steady advance. The slowest things were one knee, which had been strained some time previously, and the middle finger of the right hand, and to these several applications of the *x*-ray were made.

The patient was under treatment from November 10, 1903, to March 20, 1904. At the latter date she seemed perfectly well, although there still remained a little enlargement of the joint of the middle finger. Now, many months after the cessation of treatment, she reports continual increase in health and strength and thinks that the greatest benefit comes after the course of treatment is all over. This answers the question often asked as to whether the benefit is not merely temporary and whether the treatment does not have to be continued indefinitely.

103 West Seventy-sixth Street.

Syphilis in the Sudan.—A. Balfour says that this disease is exceedingly prevalent in the Sudan. In the time of the Dervishes it was considered rather an honor to have acquired infection. A lad was not a man till he had developed a chancre. The results of this ignorant and pernicious *régime* are deplorable. Patients do not visit the hospitals till they are masses of ulceration and necrosis. True, they make use of tureba, a native preparation of mercury found locally, and they even fashion cones for fumigation with it, but their treatment is not conducted on sound principles and is probably more harmful than beneficial. Education, combined with proper sanitary measures, is the only remedy. The Sudanese are fond of their children, and if they could be made to understand how frequently they are themselves to blame for the pitiable condition of their offspring, be taught the dangers and crippling effects of the unchecked disease, and be instructed how to avoid acquiring it and how much can be done by proper treatment when it is acquired, a great step would have been taken to ameliorate their sad condition.—*Report of the Wellcome Research Laboratories at Khartoum.*

THE PROSTHETIC TREATMENT OF FRACTURE OF THE MANDIBLE.

By FRANCIS ASHLEY FAUGHT, M.D., D.D.S.,
PHILADELPHIA, PA.,
ASSISTANT ORAL SURGEON, PHILADELPHIA HOSPITAL.

Fracture of the inferior maxilla or mandible is the most common fracture occurring among the bones of the face. This results from its prominent position, its large size and its superficial location.

Fractures are either simple or compound; simple, when they do not communicate externally, and are associated with a minimum involvement of the adjacent soft tissues;—compound, when the tissues between the bone and the skin, or mucous membrane, are so destroyed that the line of fracture communicates with the air. Either class may be complicated by comminution of the bone or by multiple lines of fracture. Fractures of the mandible are extremely likely to be compounded into the mouth, because of the close relation of the mucoperiosteum to the bone; less frequently an external opening may exist through the skin, and in rare cases the pressure of both an internal and an external opening will allow the escape of saliva through the wound, upon the face. The fact that fractures of this bone are not more frequent is due to its extreme mobility, the strength and density of its structure, and the great elasticity afforded by its arched shape. Fracture is usually the result of traumatism, generally from blows upon the face with the fist, or from kicks of large animals; less often from falls, the impact of heavy missiles, or from gunshot injuries.

Fractures of the alveolar process are very common, occurring with great frequency during tooth-extractions, portions of the alveolus being loosened or entirely torn away without involving the body of the bone. Falls upon the chin may result in a similar condition by forcibly driving the teeth into their sockets. Such fractures are of little importance, as they give no trouble and usually heal without special treatment.

Of the complete fractures of the mandible, one just anterior to the mental foramen, through the socket of the canine tooth, which is the weakest part of the bone, is of most frequent occurrence. Fractures in other parts of the bone occur in the following order of frequency: between the cuspid tooth and the angle of the jaw; between the symphysis and the cuspid tooth; at the angle of the jaw; and at the symphysis. Fractures above the angle are very rare; they may occur through the rasmus; at the neck of the condyle; or through the coronoid process.

The universal concomitant of fracture is pain—sudden, sharp, and usually continuous; this is soon followed by swelling at the site of the injury, the jaws become fixed, and in the course of forty-eight hours discoloration appears in the immediate region. All attempts to open the jaw, to masticate, or to swallow cause an exacerbation of the pain. The swelling and displacement usually cause facial deformity, which is evident on inspection. The normal occlusion may be altered or entirely destroyed, and upon motion of the fragments, one upon the other, crepitus will usually be elicited. Fractures through the tooth-bearing region may cause the loosening or entire loss of one or two teeth. Pressure externally along the body of the bone will develop a point of tenderness corresponding to the line of fracture.

Displacement is naturally greater in the compound than in the simple variety, and greatest when the fracture is multiple. The amount of displacement also varies with the site of the fracture and with the force and direction of the blow; being slight in fractures occurring at or near the symphysis, increasing as the line of fracture passes laterally until the angle is reached, beyond which the splinting action of the muscles attached to the part prevent much displacement. In fracture of the neck of the condyle, the condyle is carried forward by the unrestrained action of the external pterygoid muscle.

As already stated fracture of the mandible is usually compound; this, however, does not materially affect the prognosis unless wound infection results in necrosis, a complication which can usually be prevented by careful oral hygiene during the process of healing.

Of all the fractures occurring in the body of the mandible, probably one-fourth are multiple, that is, there exists a second line of fracture not communicating with the original one. This fact should not be overlooked, and search should always be made for the condition. One line of fracture being found in the region of the canine tooth, the second will probably be found at or near the gonion on the opposite side.

The prognosis in fracture of the mandible is generally favorable except in extreme old age. Complications, though infrequent, must be guarded against by frequent cleansing of the wound and mouth, and removal of fragments of bone which show the slightest tendency to produce suppuration. In the average case, bony union occurs in from five to six weeks. Should the completion of this process be delayed much beyond this time, search must be made for the cause, which will commonly be found to consist in a failure to obtain absolute immobility and accurate adjustment of the parts. The latter condition interferes greatly with callous formation, by allowing the soft tissues to become interposed between the broken ends of the bone. Failure to unite may also be due to circulatory or nutritional disturbances caused by injury to blood-vessels or nerves at the time of the accident. Finally, the presence of constitutional disturbances, such as pregnancy, syphilis, lactation, mineral poisoning, or typhoid fever, may be accountable for delayed or non-union. These complications should always be borne in mind, for, though extremely rare, they may be of considerable value medico-legally.

A form of pathological fracture is sometimes met with, the result of previous bone disease, which has so weakened the bone at some point that it yields readily to a strain or to mild traumatism. These fractures usually occur in bones that have previously been the seat of necrosis caused by the mineral poisons, syphilis, or malignant growths.

Briefly stated, the treatment consists in the application of a fixation appliance, after the careful reduction of the fracture, and its maintenance within the mouth for a period of about six weeks. The mandible, prominently situated as it is and affording attachment to some thirty muscles, and being intimately associated with all the movements of speech and mastication, will be seen to require treatment best calculated completely to restore its functions, and this in as short a time as possible. With the methods at our command at the present time, these requirements can practically be fulfilled in the majority of cases when the line of fracture is anterior to the last tooth.

The use of the upper teeth as a splint and guide for maintaining the fragments in place, with the aid of a bandage, except in special cases, is to be condemned on the ground that it greatly limits the motion of the jaws and dooms the patient to a soft

diet and to speechlessness for a period of five or six weeks, gaining, at the most, imperfect fixation and an uncertain result. The commonly used metal or vulcanite interdental splint is open to the same objections, for, although it affords firmer fixation, it greatly limits the functions of the mandible. The Garretson splint, adjusted to the lower jaw alone, securing fixation by means of extension bars passing between the lips with a bandage passing between them and under the chin, embodies the right idea in that it allows for free motion of the mandible as a whole; it is nevertheless bulky, and also interferes greatly with mastication. All the above methods depend for their fixation upon some form of external head-gear, which at best requires constant attention, and is unsightly and a constant annoyance to the patient, while in restless and vicious children and in the insane it is impossible to keep it in its proper position.

The continued use, for any length of time, of a fixation bandage passing around the front of the chin, may result in positive and permanent harm, as the following case demonstrates.

The patient, a man, previously in good health, and with no recognized oral deformity was admitted to the hospital suffering from a fractured jaw, the result of a fall. At the time of admission he was given the routine hospital examination; the condition was recognized and a Barton bandage applied. Some weeks later, in the fall, he came into the hands of the Dental Staff still wearing the Barton bandage, when the following condition was noted. Externally the facial lines, although fairly symmetrical, showed marked contraction and recession about the chin; within the mouth, the right canine tooth was found almost directly behind the left canine and internal to it, showing a displacement and overlapping to the extent of nearly six teeth. There was fibrous union with the bones in this position which caused such contraction of the floor of the mouth that there was no room left for the tongue. Corrective treatment was offered but refused. It will be seen by this illustration that unless carefully watched, the constricting action of a bandage, without proper fixation of the parts by other means, is capable of entirely defeating our best efforts, and of causing permanent deformity.

The metallic cap splint affords a certain and effective means of securing fixation, while possessing none of the objectionable features of the previously mentioned fixtures. The preparation of this splint requires but average mechanical skill, and can be constructed and cemented into place in a few hours. The first requirement is an accurate cast of the teeth of the fractured jaw, best obtained by taking an impression in plaster from which the plaster cast is made. Plaster-of-paris is preferable to the other impression materials, because it can be used without the aid of a metallic impression-tray, which at best is very cumbersome and, if used here, would add greatly to the patient's discomfort. Another advantage of this material is its quality of fracturing sharply without changing shape when it has once become hard, a fact which is taken advantage of when removing the impression from the mouth.

When the impression has become thoroughly hardened in the mouth it is split into pieces with a sharp knife and removed piecemeal; afterwards these fragments are fitted together and held in position by a little sticky wax. The cast is made by pouring plaster, mixed to the proper consistency, into this impression, and when the cast is hard, cutting away the plaster of the impression from around it. A cast made after this manner will give us an accurate facsimile of the teeth in the patient's mouth. An impression in wax or modeling-compound is next taken of the upper teeth and another plaster cast is made from this. With the cast of the upper teeth for a guide, the cast of the fractured jaw is sawn apart so that the teeth can be placed in their former normal occlusion with their antagonists. This corrected cast is made whole again by the aid of a little freshly mixed plaster added to its base. The cast as it now stands, represents approximately the form and shape of the mandible before injury. This cast is now ready for the construction of the splint, according to the following method: Varnish the cast and when dry prepare a sand matrix and make a metallic die (for this purpose Babbitt metal is preferable to zinc because it does not contract on cooling) upon which, after cooling, a counter-die of lead is made. Between the die and counter-die the splint is swaged. This may be made of gold, platinum, silver or German-silver, as fancy or the pocket-book of the patient dictates. After careful fitting and adaptation to the cast, all prominent corners are filed away, the edges of the splint are trimmed to conform to the gingival festoon, and the whole carefully polished. The internal surface is grooved and etched with a sharp-pointed instrument to form better attachment for the cement.

During the cementing process, it may become necessary, if fibrous bands exist, or if the muscles are resistant, to resort to an anesthetic. This question must be decided in each individual case. After placing the patient in a convenient position, the mouth is prepared for the operation of inserting the splint. The teeth about to receive the splint are thoroughly and carefully dried by means of cotton-rolls and napkins, the final drying is accomplished with chloroform which is wiped over the teeth and then evaporated by a current of warm air under pressure. Oxyphosphate cement, mixed to the consistency of cream, is now applied to the teeth and to the splint, which is filled one-third full of the mixture, when it is immediately forced firmly down upon the teeth and held there until the cement is thoroughly set; this will require at least a half hour. All excess of cement should be removed from the gingival margin to prevent unnecessary irritation at that point.

A splint carefully constructed and inserted, if all moisture has been absolutely excluded during the operation, will remain firmly in place until it ceases to be of service and is removed from the mouth prior to the dismissal of the patient.

From the foregoing description it will be noted that this splint introduces the least amount of foreign substance into the mouth and is contained entirely within the mouth, thus reducing the patient's discomfort to a minimum, at the same time affording a rigid support for the fractured bone, while permitting of free movement of the mandible with easy access to the oral cavity from the very first.

For the first week the patient should remain quiet and make free use of antiseptic mouth-washes. Ice held in the mouth and allowed to melt there will greatly add to the patient's comfort and will also have a tendency to reduce inflammation.

The most convenient method of applying cleansing and antiseptic solutions to the mouth is by means of the atomizer. For this purpose, through the kindness of Mr. Joseph Ferguson, Jr., optician, I have had modified the ordinary De Vilbiss atomizer, with the vertically ajustible tip, so that it can be moved in a horizontal plane, thus making it practical to flush out all parts of the mouth, including the interspaces, by means of one atomizer. With this atomizer I employ air under a pressure of

twenty pounds to the square inch. Subsequent treatment, in the average case, is quite simple and can be left largely in the hands of the patient, after the likelihood of complications has passed.

In those rare fractures occurring above the angle of the jaw, little can be accomplished other than attempts at moderate fixation and rest, depending for retention upon the splint-like action of the muscles attached to this part.

In fracture of the neck of the condyle, the condyle is drawn forward and cannot be returned to its normal position because of muscular tension. It becomes necessary, therefore, to bring the body and ramus of the bone forward to meet the displaced fragment. This may be done with wire ligatures passed from upper to lower teeth, or by means of an interdental splint made upon casts, articulated according to the modified position of the jaws required to obtain approximation of the fragments.

Fractures occurring in the body of the bone in edentulous subjects are very difficult to treat, inasmuch as they are hard to immobilize, and the results are often unsatisfactory. The only method at our disposal here, besides cutting down upon and wiring the fragments, is the insertion of an intermandibulo-maxillary splint, made upon plaster casts of the patient's jaws.

The use of silver-wire ligature passing through holes drilled in the body of the bone and bridging the site of fracture, is only to be resorted to after all other methods have failed, because practice has taught us that many cases so treated result in failure, and also because it is poor surgery to subject the patient to the increased danger of infection and necrosis accompanying this procedure without offering any greater chances of recovery.

ACUTE INTUSSUSCEPTION IN AN INFANT; RESECTION OF GANGRENOUS INTUSSUSCEPTUM; MURPHY BUTTON ANASTOMOSIS; RECOVERY.

By EDWARD W. PETERSON, M.D.,

NEW YORK

ASSISTANT SURGEON TO THE POST-GRADUATE HOSPITAL, AND TO THE BABIES' WARDS OF THE POST-GRADUATE HOSPITAL,

The patient, whose history follows, was admitted to the Babies' Wards on September 30, 1904, and was operated upon before the matriculates of the Post-Graduate Medical School.

Ida Ahrens, aged 4 months and 20 days, of German-American parentage, breast-fed, well nourished, and healthy. Had never previously been sick. September 28, was somewhat restless and fretful, and the following day suddenly became very ill. After one large fecal movement, she began to have frequent discharges of blood and mucus, without the passage of gas or feces, also paroxysms of colicky pains and tenesmus, and occasionally spells of vomiting. A physician who was called in diagnosed the case as "bloody dysentery." The mother, becoming alarmed at the increasing severity of the symptoms, brought the child to the hospital on the afternoon of September 30.

On admission the infant was very restless, constantly whining or crying out; facial expression anxious and uneasy; eyes "tired looking" and somewhat sunken; tongue dry; abdomen slightly distended, but no visible tumor present; thighs flexed on abdomen. The extremities were cool, the abdomen hot, somewhat rigid, and tender on pressure. An elongated tumor could be felt running from the right upper quadrant of the abdomen, across in the direction of the transverse colon, and then downward into the left iliac region. Rectal examination revealed a softened cylindrical tumor about two inches above the sanus; the examining finger when withdrawn from the bowel was covered with bloody mucus. The temperature was 102° F., pulse 146, and respiration 40.

A diagnosis was made of acute intussusception, of probably not less than thirty hours' duration, and preparation for immediate laparotomy was ordered. At this stage any other measure was deemed not only useless, but dangerous.

Operation.—A two and one-half inch incision was made through the right rectus muscle; a small amount of serous fluid escaped when the peritoneum was opened. Examination of the tumor confirmed the diagnosis of intussusception. Beginning at the distal end, or at the apex of the intussusceptum, with great care, the reduction was attempted. The gut was acutely congested and edematous, and the serous coat readily tore. Firm adhesions between the last inch of ileum and cecum, with beginning gangrene, rendered impossible the complete and successful reduction of the invagination. Removal of the gangrenous gut was decided upon. Four inches of the ileum, the cecum, and an inch of the ascending colon were resected, the mesentery having first been ligated. Then an end-to-end anastomosis, by means of a small Murphy button, was made. After attending to the gap in the mesentery, the abdominal incision was closed in layers, with catgut, and reinforced by three sutures of silkworm gut, through all the layers except the peritoneum. Dressings and bandage were applied, and the patient was returned to bed in a profound state of shock. A glance at the chart will show the stormy character of the convalescence. Respirations were exceedingly rapid and temperature high, immediately following the operation. The pulse, while very weak, did not show depression corresponding to respiration and temperature. Stimulants were freely used to combat the shock. Vomiting was frequent and annoying for the first fifteen hours, after which time it gradually abated. Only one dose of opium (5 minims of paregoric) was given, and that not until vomiting had ceased. The bowels moved spontaneously on the afternoon following the operation. A moderately severe secondary enteritis soon developed; this was treated with astringent intestinal antiseptics, and bowel irrigations. On the fourth day the temperature went up, and the child seemed to be in great pain. In looking for a cause for this, the examination revealed the fact that the button had passed down to the anus and was there lodged. The removal of the button was followed by an immediate improvement in the symptoms. The abdominal wound was dressed on the fifth day, and the lower end of the incision was found to be infected. This infection promptly cleared up, and the wound was entirely healed by the fourteenth day. The patient was discharged cured on the fifteenth day after operation.

To review the history of this case: A healthy, well-nourished infant suddenly became very ill, with paroxysmal, colicky pains, tenesmus, bloody stools, vomiting, fever, and collapse. Examination of abdomen by bimanual rectal touch showed a "sausage-shaped" tumor. It will be seen that this patient presented the classical symptoms and fulfilled in an ideal way the text-book requirements of acute intussusception. Operation confirmed the diagnosis. The ileum, appendix, and cecum were telescoped into the colon. On account of adhesions and beginning gangrene the invagination could not be completely and successfully reduced, so a resection was made with an end-to-end anastomosis between the ileum

and ascending colon. After operation, the severe shock, high temperature, and vomiting, enteritis, toxemia, etc., gradually disappeared and recovery ultimately ensued. (An interesting feature of the case was the early passage of the Murphy button.)

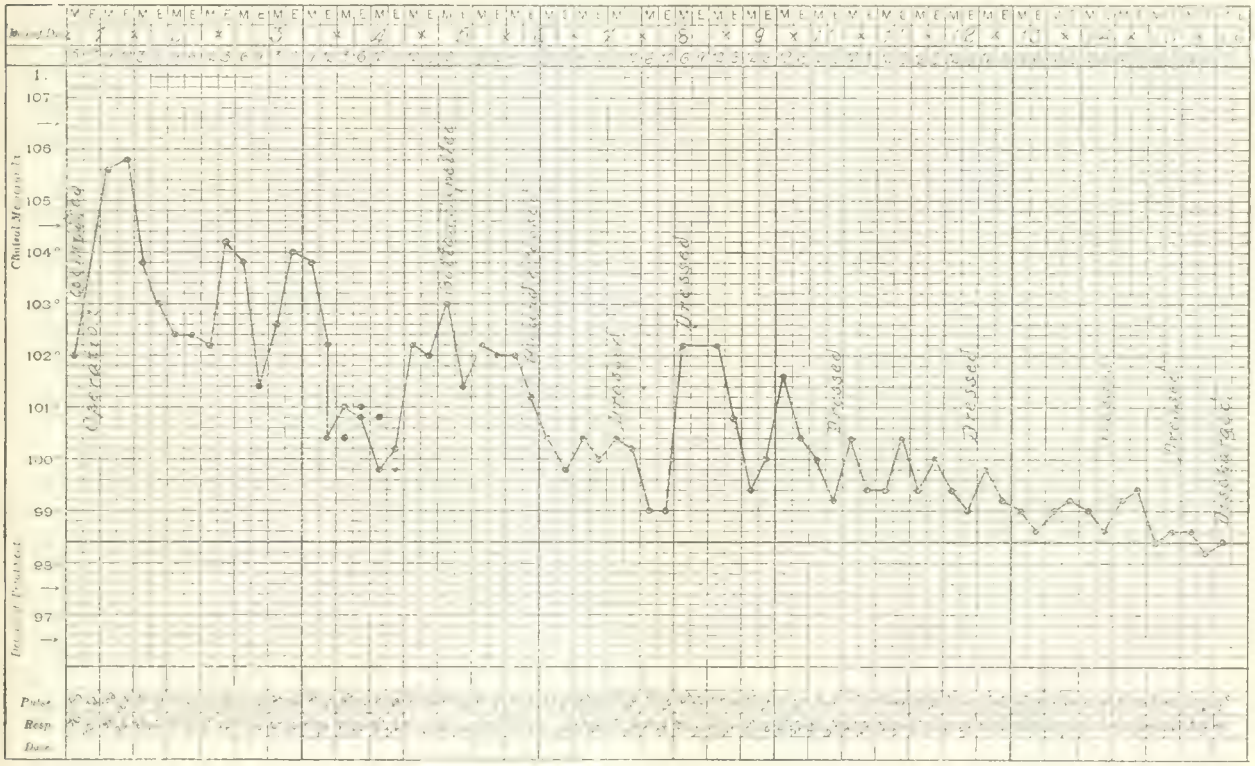
Unless acute intussusception is recognized early and treated promptly, the result is almost always fatal. Spontaneous reduction has been known to take place. Cases have recovered after sloughing of the intussusceptum, firm adhesions forming at the neck of the intussuscipiens. Such results are, however, never to be awaited or expected. If a case is seen early, say not later than six or eight hours after a diagnosis is possible, an attempt should be made by means of posture, gentle manipulations, and enemata to reduce the intussusception. Air inflation is to be condemned. By such means it may be possible to reduce an invagination of the "colonic" variety. However, it seems improbable that such measures would succeed in the "ileocecal" or "enteric" types. The sooner we come to regard acute intussusception in the light that we look upon strangulated hernia and fulminating appendicitis, that is,—as a condition demanding immediate operative interference, the more lives will we save. Early laparotomy is the least dangerous, and by all odds the most successful method of treatment.

There are points about the operation itself that deserve attention. The work should be performed quickly, or rather with "speedy deliberation." As three-fourths of all cases are of the "ileocecal" variety, the incision should be made through or to the outer margin of the right rectus muscle. In relieving the invagination, it is best to commence at the apex of the intussusceptum, and carefully "back up" to the point where the trouble originated. If traction is made on the proximal end of the invagination, the gut is apt to be torn at the neck of the intussuscipiens. Removal of the appendix is positively indicated in nearly all cases of "ileocecal" invagination, and it is a good point to make appendectomy a step of the operation. In closing the wound, one should reinforce the catgut sutures with through-and-through silkworm gut sutures, as the abdominal wall is subjected to a considerable strain.

The post-operative treatment is of great importance. The immediate danger is death from shock, and free stimulation is indicated to overcome this condition. The next danger is due to the secondary enteritis and toxemia, which are present to a greater or less degree in all cases of intussusception. If opium is systematically employed, the enteritis is aggravated, and the toxemia accentuated. It is better to give a mild laxative, and to follow it with astringent intestinal antiseptics, and bowel irrigations. Under such management the condition will improve.

When this article was written, a careful search through the literature justified me in the belief that this was the first successful operation, in an infant, for the relief of intusssusception, in which resection of the gut was performed. Since that time, however, Dr. Jacob Frank of Chicago, in an article in the *Annals of Surgery* for February, 1905, has referred to a case of intussusception in a nine-months-old infant, in which an anastomosis was made and recovery followed.

63 West Fifty-second Street.



THE USE OF EXTRACT OF DICHONDRA AS A BACTERICIDE IN DIPHTHERIA.

By M. ARAMIAN, M. D.,
NEW YORK.

It is a well-known fact that the treatment of diphtheria antitoxin acts only against the toxin and has no action whatever against the Klebs-Loeffler bacilli, that produce the toxin; so these microorganisms remain in the throat as long as they used to remain before serum therapy was discovered; therefore, it is necessary to keep children under quarantine for a long time, regardless of the fact that they have recovered from the disease. For long a search has been made for some means of shortening the period of confinement and isolation. Almost all of the known antiseptics and caustics have been tried

for this purpose, with more or less success, but it has been found that all of them act only superficially, forming a layer of coagulation, under which the microbes still remain alive. In the extract of dichondra,* as I hope to demonstrate in this article, I believe a true remedy has been found, capable of destroying the specific bacilli. It destroys completely the bacilli of diphtheria, usually within two to five days, without the slightest irritation, for it is not a caustic, and, furthermore, can produce no harm if swallowed, even in large quantities, by the children under treatment, for it has no toxic properties.

It has been proven by various bacteriologists in France that its peculiar toxic action is directed solely against the Loeffler bacilli, and that it has no action on other microorganisms that breed in the throat during the diphtheria period and which disappear with diphtheria bacilli, for it is the latter that render the former virulent and active. This remedy has been tried since 1894 in the hospitals in Paris, and on my patients, by two methods: (1) alone, and (2) in conjunction with antitoxin. It has been perfectly successful in both ways. Success is always complete when it is possible to reach all the affected parts with the remedy, but when this cannot be done easily, then it is necessary to use antitoxin and with it to use dichondra, in order to destroy the bacilli as speedily as possible in the throat and the parts which may conveniently be reached with the remedy.

While antidiphtherin has no direct action against the diphtheria toxin, when used alone, it surely stops the further production of the poison by killing the specific bacilli that produce it, and if by that time some amount of the toxin has penetrated the general circulation, it will soon be eliminated by the natural process of the organism. A certain quantity of toxin is required to produce complications; if these complications have not yet taken place, when antidiphtherin is resorted to, they will not occur afterwards, for the bacilli will cease to produce toxin after the first application of the remedy.

It remains for the physician, therefore, to take advantage of its germicidal properties, using it according to the case, either alone or with antitoxin. In all circumstances it is certain to shorten the period of the illness, thus filling entirely the want which antitoxin leaves to be filled. In short, antidiphtherin, when used in conjunction with antitoxin, cures diphtheria, usually in two or three, sometimes five days, and never exceeding seven days, in very severe cases, while when antitoxin is used alone the duration of the disease is habitually from fifteen to fifty days, and even more (I have seen cases in which the bacilli were persisting six months and more), since the sufferers are not considered definitely cured while bacilli are present in the throat, as they are yet dangerous as contagion bearers. In some light cases, especially in cases of pure diphtheria, the bacilli may disappear in a few days without the use of antidiphtherin; but these cases are exceptional, while with the use of antidiphtherin, the bacilli are destroyed in a short time in all cases, whether light or severe, mixed or simple. Antidiphtherin is a solution of one part of the extract of *Dichondra brevifolia* (convolvulacea family) in three parts of glycerin. This extract is obtained from the seeds and stems of the plant. It is, therefore, a simple and harmless vegetable remedy, which owes its specific action to the plant above mentioned. It is a thick liquid of a dark brown color and slightly bitter taste. I have made inquiries of the director of the botanical gardens in Bronx Park, in this city, and have been informed that there are several species of dichondra growing in the United States, such as orgentia, carolinensis, villosa, parvifolia, etc., and Dr. H. Rusby, professor of botany in the College of Pharmacy of Columbia University, tells me also that he thinks all species of dichondra have more or less the same properties. But my researches so far have only been on *Dichondra brevifolia.* Children who are cured by means of antidiphtherin only are liable to get the disease a second time, if kept in contact with others having diphtheria; because antidiphtherin has not the immunizing power that antitoxin possesses. But we can positively overcome this inconvenience by applying antidiphtherin once a day, no matter how well the child may be while in dangerous surroundings.

When antitoxin is used with antidiphtherin, the former can without any inconvenience be used in smaller quantities than when exhibited alone; in this way it is not only perfectly safe, but it has the decided advantage of preventing complications (urticaria, erythema, arthralgia, nephritis, cardiac disturbances, etc.), resulting from an excessive use of the antitoxin, which, as we know, is unreliable in streptococcic diphtheria and contraindicated, in large doses, in albuminuria.

Extract of dichondra, used internally, has a slightly diuretic and laxative effect.

Bacteriological Investigations.—The extract of dichondra, when put, in quantities gradually increasing, in several tubes, each containing a pure culture of the Klebs-Loeffler bacilli, in saccharinated bouillon, diminishes their number and later totally destroys them. The tubes containing the bacilli were exposed to 35° C. for two days. The control tubes showed marked increase in the number of the bacilli, while those containing more or less extract of dichondra showed decrease in their number, according to the quantity of the bactericide in each tube. In the tubes which contained a small amount, a few bacilli were found, and in order to ascertain if these bacilli retained their virulence, I inoculated two guinea pigs with four drops per 100 grammes of weight, one with the contents of the tubes containing the smallest quantity of the extract of dichondra, the other with the contents of a control tube containing none of the extract. The animal inoculated with the contents of the tube containing pure culture died in twenty-four hours, while the other remained sick for only two days and recovered completely. These experiments have been repeatedly made and always with the same results. In the treatment of diphtheria antidiphtherin can be applied quite frequently without any inconvenience, but as a rule four to six applications a day are sufficient. Oftener used it will give better results, especially in severe cases. In every severe case it is necessary to repeat the applications every two hours, and in dangerous cases every hour, without disturbing the child during sleep. Its mode of application is simple: Take a piece of absorbent cotton, the size of a hazlenut, with a cotton holder, dip it

*The solution of one part of the extract of dichondra in three parts of glycerin has been named by me antidiphtherin in view of its specific action against diphtheria (see *Journal de Médecine de Paris,* 1903, page 260, and *La Revue Médicale,* 1903, page 273). In order to prevent confusion I will continue to call this solution antidiptherin, as this name explains better its usage, especially because the combination of one part of extract of dichondra with three parts of glycerin acts better, preserves it from deterioration and becomes the most convenient form of an antidiphtheritic medicine. It is expressly to be noted, however, that this is in no sense a proprietary name, being employed only as a matter of convenience to designate a mixture of the given strength.

into antidiphtherin and carry it to the throat of the patient, reaching as far into the fauces as possible, press the contents of the cotton upon the diseased parts uniformly, firmly, and quickly. The cotton must be well saturated with the medicine, so that the contents will spread around the throat freely.

After the application it is necessary that the child should not be given anything to eat or drink for at least half an hour, in order not to weaken the effect of the medicine. In nasal diphtheria, the applications must be made within the nose with a swab of cotton. In croup it must be applied in the same manner as in performing intubation, employing a small piece of cotton, according to the age of the patient. These applications to the larynx can be safely neglected if the patient has already been treated with antitoxin, and in these cases it is sufficient to make deep applications in the pharynx only. This should be done, even if false membranes are not present, for it has been shown that the Klebs-Loeffler bacilli are always attracted to the pharynx. The most essential point to be observed is that it should not be applied less than four times a day in light cases, nor less than six times in severe cases. Another point to observe is that the applications must be continued until all the redness on the diseased parts of the mucous membrane disappear, which is usually a sign that the bacilli are destroyed; but this affords no absolute assurance, and, therefore, the applications must not be stopped before bacteriological confirmation of the result is obtained.

Experimental Observations in Europe and America.—I began my experiments in Europe in 1894, and from that date I have had 109 cases in Europe; 53 in my private practice; 2 at the Hôpital des Enfants Malades, Paris, 1894; 27 at Hôpital Trousseaux, Paris, 1902; 12 at Hôpital Hérold, Paris, 1902-1903; 15 at Hôpital Trousseaux, Paris, 1903 (See *Journal de Médecine de Paris,* 1903, page 260, and *la Revue Médicale,* 1903, page 273).

Among my private patients I had two cases ending fatally. Both children died the day following my visit, the disease being too far advanced and complicated, in one case, with bronchopneumonia, in the other with myocarditis. The remaining patients were cured in from two to five days, according to the severity of the cases.

Of these 53 cases, 27 were cured by antidiphtherin alone, for at that date antitoxin was not yet discovered. Beside these twenty-seven cases, the two patients that were cured in the Hôpital des Enfants

Malades were also treated without antitoxin. One of these was a girl, eleven years old, with slight and pure diphtheritic angina. She entered the hospital on June 11, 1894, and left cured on June 16, or in five days. The other case was that of a boy nine years old, suffering from infectious and mixed diphtheritic angina, complicated with croup and nasal diphtheria; he entered the hospital June 11, 1894, and left completely cured on June 18, or in seven days. It was after these two cases were cured that Dr. Roux first published his observations on antitoxin. After this date I began to administer antitoxin with antidiphtherin, which gave me better results. The following twelve cases, for example, treated in Hôpital Hérold, will help to convince the reader:

Of the above mentioned cases, only Louise Normand was treated without antitoxin.

The cases treated in the Hôpital Trousseaux, 27 in 1902 and 15 in 1903, 42 cases in all, gave exactly the same results as those cases treated in Hôpital Hérold; for this reason I do not think it necessary to give here detailed histories; these are printed at length in the journals above mentioned. Of these 42 cases treated with antidiphtherin, only three were treated without antitoxin. These three were light cases and the disease was localized in the pharynx; two of the patients were cured in two days and one in three days.

In New York I have endeavored to have the medicine tried in the hospitals, in order to show to my American colleagues its advantages, but I found this impossible, without having first tried it on private cases. It was with great difficulty that I was able to secure the assistance of a few confrères who were kind enough to try antidiphtherin in their private practice. The results are as follows.

Case I.—Minnie G., treated by Dr. Avac Cutujian, 71 Lexington avenue; first culture examined by the Board of Health under No. 8777, shows the presence of Klebs-Loeffler bacilli. On this case Dr. Cutujian reported as follows: "Minnie G. was seen by me on May 16, 1904. Clinical diagnosis was diphtheria. I took the culture specimen on the above date, injected antitoxin (2,000 units) and made local application of antidiphtherin (case being diphtheritis laryngeal croup). On May 17, 18, and 19 one application of antidiphtherin was made each day. On May 20, 21, and 22 four applications of the antidiphtherin were made each day. On May 23 a secondary culture was taken and it did not show any Loeffler bacilli. In this case there occurred a total disappearance of the diphtheria bacilli in seven days; and as previously I never had a case in which diphtheria bacilli disappeared in such a short time, I am led to believe that the use of antidiphtherin shortens the duration of Loeffler bacilli life."

Case II.—Bertha P., treated by Dr. Swift, 121 East 26th street. The patient suffered from infectious and severe diphtheritic angina, complicated with croup. First culture examined by the Board of Health, on May 16, 1904, and under No. 8,778, shows the presence of Klebs-Loeffler bacilli. On the above date the patient received 3,000 units antitoxin and applications of antidiphtherin were made only in the pharynx, every four hours. After eight days, on May 24, a secondary culture was taken and it did not show any Loeffler bacilli; the throat was clear before, but no culture was taken until the above date.

Case III.—Annie C. had the usual diphtheritic angina; she was treated by Dr. H. P. Swift, 121 East 26th street. First culture examined by Board of Health on July 5, 1904, under No. 11,299, showed the presence of bacilli. Dr. Swift reported as follows: "This case was seen for the first time July 4. Antitoxin (3,000 units) was injected that evening. The applications of antidiphtherin were made on that date. The case was of moderate severity; the child was ill three days, membranes extended over both tonsils. Applications were made

every four hours on July 5 and 6. The membranes were very slight on July 6 and had disappeared entirely on July 7. I left for my vacation on that date, and the second culture was not taken by the Health Department Inspector until July 16, which was clear."

CASE IV.—Meldrea H., treated by Dr. H. S. Abkarian, 167 Glenmore avenue, Brooklyn, had severe diphtheritic angina. First culture examined by Board of Health under No. 4,483, showed the presence of the bacilli. Regarding this case, Dr. Abkarian writes the following: "Many thanks for your antidiphtherin, which you sent to me on July 29. I made three applications a day on my patient, on July 28, 29, 30, and 31. A culture was taken on August 2, six days after I commenced the use of antidiphtherin, and the result you will find on the other side, and I can assure you it is very unusual."

CASE V.—Sadie F. was treated by Dr. Franklin Dunseith. On receiving the last report of the culture of his patient from the Board of Health, under No. 14,429, Dr. Dunseith writes the following: "I first saw this case on the evening of October 17, The patient was a girl of 13 years, sick four days, membranes on both tonsils, uvula, and soft palate; temp., 105°; pulse, 140; severe infection. The culture showed Klebs-Loeffler bacilli present. Antitoxin (5,000 units) was injected October 17, 1904, at 6 P.M. In four days the membranes had disappeared. A culture on October 24 showed no Klebs-Loeffler bacilli. The only medication to the throat consisted in applications of antidiphtherin."

CASE VI.—Martin M. was treated by Dr. Avac Cutujian, 71 Lexington avenue. First culture examined by the Board of Health under No. 15,374, showed the presence of diphtheria bacilli. Dr. Cutujian reported as follows: "The diphtheria case of this report was seen by me and culture taken on November 9, 1904. On November 10 I received the report, showing the presence of Klebs-Loeffler bacilli. After applying antidiphtherin for four days, four times daily, I took a secondary culture on November 16. This specimen did not show the presence of any diphtheria bacilli. In six days the patient was free from diphtheria, and the patient's room was ready for fumigation. I shall still use this preparation for further corroborative evidence, feeling that its systematic use in diphtheria cases is going to aid the physician in materially shortening the quarantine period."

CASE VII.—This case was treated by Dr. F. Dunseith, 354 West 42d street, who has written me the following: "In case of Edna B., on January 13, I found both tonsils covered with membranes; culture showed it to be a true case of diphtheria; temp., 103°; pulse, 95. I applied antidiphtherin on January 14 and 15. A culture taken January 16 showed no Klebs-Loeffler bacilli; no other application was made to the throat but antidiphtherin. Antitoxin (3,000 units) was injected on January 13. No other medication other than above stated was employed. The fever subsided January 15."

CASE VIII.—This case was also seen by Dr. F. Dunseith, who wrote as follows: "The last case of diphtheria in which I used antidiphtherin was the most remarkable case of M. D., six years old. Culture showed it to be a true case. On January 18, 1905, on the appearance of the membrane on both tonsils, soft palate, and uvula (temp., 105°; pulse, 160), 5,000 units of antitoxin was immediately injected. Antipyretics and heart stimulants, iron, chlorine, and mercury were given, with H_2O_2 to the throat, but all to no avail, the membrane increasing. On January 20 a second injection of 5,000 units of antitoxin was given. On January 23 I stopped all treatment and began with antidiphtherin applications every hour; the fever subsided in twelve hours and the membrane had disappeared on January 25, when culture showed no Klebs-Loeffler. On January 27 patient was quite strong and there was no return of membrane."

Conclusions.—1. It is necessary to treat diphtheria with both antitoxin and antidiphtherin. This is the best method.

2. Physicians who are opposed to the use of antitoxin will be better satisfied with antidiphtherin than with any other remedy.

3. Applications should be made not less than four times a day in any case, and should be continued until the results of bacteriological examinations show that the bacilli are completely destroyed.

Coughs and Colds.—William F. Waugh suggests giving strychnine arsenate and amorphous aconitine, 1-134 gr. of each, repeating every 15 minutes till the effects of one or the other are manifest in slowing pulse or increased arterial tension. If the patient is below par, digitalin, gr. 1-67, may be added to inforce the strychnine. If the pulse is full and fast, and the emunctories closed, veratrine is added, gr. 1-34, till slight nausea or gastric burning indicates that enough has been taken. By this time the "cold" will be a thing of the past. Some of the blood vessels are dilated and contain more blood than is normal while others are contracted, and have too little blood. Hence, the above treatment will reach this difficulty. The absolute stoppage of all food and drink—water, too—gives the best results when trying to abort a "cold." The greatest of remedies for a tight dry cough is found in ipecacuanha—not the crude drug, but emetine. This is also an eliminant and acts on the liver even better than calomel does. In rare cases when there is an idiosyncrasy against all forms of ipecac, apomorphine may be used. If the patient is robust and there is some fever, lobelin is perhaps safer. Codeine is a better sedative for irritative coughs than morphine. The writer, however, is averse to opiates in all forms. The accessories, hot mustard foot-baths, quiet, the application of rubefacient liniments to the chest, and so on, should not be neglected.—*The Canadian Journal of Medicine and Surgery.*

Have Ankylostomiasis Patients Any Peculiar Marking on Their Tongues?—T. M. Russell Leonard carefully examined 362 hospital patients, and found the ova of the ankylostoma in the feces of 112 of this number. Of these cases, eighty-nine, coolies and West Indian negroes, presented the pigmentation on their tongues. The remaining twenty-three cases were white Barbadians, and showed no pigmentation. The pigmentation varies in color from a faint blue to a blue-black, and is seen in minute points or in areas on the tip or sides of the tongue, and is found only in the West Indian negro and in the immigrant coolies and their children, and not in the cases of Europeans or Barbadians or pure whites. Ground itch, due to the penetration of the skin by the embryo ankylostoma, leaves in a large number of cases a peculiar mottling of the skin, and the points or areas of pigmentation seen on the tongue may be due to the injection taking place there, the embryo parasite being conveyed to the mouth on the hands or in the food of the patients. The cases exhibiting this pigmentation, did not in many instances show marked anemic symptoms, and the writer sees no connection between the pigmentation and the degree of anemia, but believes that the former indicates only that ankylostoma are present. For on the removal of the parasites, and subsequent treatment with iron and arsenic, and a generous diet, the pigmentation becomes fainter and often finally disappears. The cases examined were of all ages. The writer believes this sign in the West Indies to be of great diagnostic value.—*The Journal of Tropical Medicine.*

New York, March 4, 1905.

TREATMENT OF RHEUMATOID ARTHRITIS.

THE condition known as chronic rheumatoid arthritis has as yet met with no very successful treatment. The methods are various but the results unsatisfactory, the explanation being that the cause of the disease is not well known, that it has a marked tendency to be progressive, and is characterized by occasional exacerbations of acute and more rapid extension. Dr. John Orr of Edinburgh writes in the *Practitioner* for February, 1905, on some methods of treating this affection.

Dr. G. W. Balfour in 1893 initiated a mode of treatment by which he claimed he could practically always arrest, and often cure the disease, and that failure was more often than not due to the patient's faulty carrying out of orders. The method may be considered under three heads, viz., treatment by (1) diet, (2) internal medication, and (3) counter-irritation. These three ways of fighting the malady must be used in combination, and if steadily employed together, the effect is usually gratifying.

The object aimed at in the dietetic part of the treatment is to give food which is easily digested and assimilated, and all red meats, including mutton and beef, are abolished from the diet list. White meats and white fish only are allowed, and these must be cooked by boiling, roasting, grilling, or in the case of fish by broiling. Sugar, and beet-sugar in particular, is forbidden, its place being taken by saxin. Potatoes, turnips, head of cauliflower, peas, and beans are also as a rule contra-indicated. Tea infused in boiling milk may be taken, as made in this manner it forms a bland, non-astringent, and innocuous combination. Well boiled porridge is good, while eggs lightly boiled, scrambled, or poached can be taken by some patients without injurious effect. Alcohol in moderate amount seems to have little influence on the course of the disease.

Internal medication consists in the exhibition of arsenic and iron in small doses for the period of three weeks out of every month; cod-liver oil is likewise decidedly advantageous in cases in which it is well borne.

Counterirritation is most usefully carried out by the employment of blisters. Each large joint has applied to it a blister once in every seven or ten days, the emplastrum cantharidis being the most certain and constant in its action. The size of blister employed for these large joints is one inch square. Small blisters may be applied to the smaller joints. The counterirritant is employed at different areas all round the affected joint. The urine should be carefully observed, and the occurrence of albuminuria will constitute a contraindication.

This treatment, says Dr. Orr, should be conscientiously pursued for two, three, or more years, and after a successful result has been attained, the diet should still be unaltered, and arsenic and iron ought occasionally to be taken. Although, however, Dr. Orr has the highest opinion of the treatment sketched above, and he judges from practical experience, he nevertheless readily concedes that other remedial agencies may be very valuable for the alleviation of intercurrent symptoms, but these, he thinks, are never curative. He is in favor of treatment by potassium iodide, sodium salicylate, guaiacum, ichthyol, external anodyne applications, and the employment of electricity, especially electric baths, and currents of high frequency. These confer temporary benefit. As to baths and mineral waters, the writer is of the opinion that, although they are of much service, it is quite possible to treat cases successfully without their aid. Dr. Orr states emphatically that by treating rheumatoid arthritis by the so-called Balfour method, a considerable amount of good can be done in the way of alleviating suffering, preventing deformity, restoring the use of limbs, and in some cases effecting a cure.

MOVABLE KIDNEY.

IN the London *Practitioner* for January, Sir Frederick Treves discusses this condition, which is conspicuously one of modern times, the first sound description being Rayer's in 1839. Post mortem it vanishes, Ebstein finding it in only 5 of 3,658 autopsies, while clinically Glénard says it occurs in 22 per cent. of all women examined.

The kidneys lie deep in the gutter on either side of the spinal column, under the seventh to tenth rib cartilages, the upper end of the left being at, and that of the right nearly at, the level of the ensiform. They lie somewhat lower in women and children. Apart from the not inconsiderable support afforded by the configuration of the gutter-like depressions, the kidneys are supported in place by the perirenal (an extension of the subperitoneal) fascia, by the important general intraabdominal pressure of the surrounding viscera, and to a less extent by the renal vessels. The peritoneal covering exercises very little effect, it having but slight hold on the fascia and fat and being easily rendered movable. Much has been said about the mobility of the kidneys with respiration, Dentu even stating that it amounts to from 3 to 5 cm., a mobility that Treves has never seen in normal kidneys. His experience is that normally with the left kidney the respiratory movement is often inappreciable, that of the right being much less even than that of the liver.

The etiology of the condition is obscure and little is definitely known about the progressive tissue changes leading to it. It is usually first discovered between the ages of 25 and 50 years. In 148 cases Glénard found it only seventeen times in men. In 126 cases it occurred only three times on the left side alone; nineteen times on both sides. While in men the right kidney is now and then displaceable, the condition must be exceedingly rare on the left side; and though such a diagnosis has been made, the tumor has usually been found to be a fecal mass

in the colon or a sarcoma of the omentum. It is more common in multiparæ, and quite a number of the patients have suddenly become thin (sometimes without known cause, sometimes following exhausting illnesses). There is considerable evidence that injury may cause it.

There is scarcely one abdominal or other symptom that has not been credited to movable kidney, from mere peevishness to agonizing renal pain. The classical picture would probably be dragging in the abdomen, indefinable discomfort, and a feeling of weakness, perhaps passing into actual pain, possibly radiating down the legs and across the back, occasionally also increased frequency of micturition, dyspepsia, flatulence, and constipation. The symptoms are increased by motion, especially jolting, leading to disinclination to stand or walk more than necessary. Yet all of these may occur without movable kidney. There is no definite relation between the degree of mobility and the clinical symptoms, and a wild kidney may give absolutely no symptoms. On the other hand the first symptom may be a torsion attack. In the symptomatology, these attacks stand alone. Usually sudden, with intense renal pain, vomiting, abdominal tenderness, and varying degrees of collapse, they may sometimes be less abrupt or even of gradual onset, and may cease abruptly or slowly.

The literature would rather encourage the idea that the only treatment is operative. Possibly the mortality of operation is not more than 1 per cent., Dentu having collected 374 cases with only four deaths properly chargeable to the operation. Keen has, however, collected 134 cases in which the mortality was 2.9 per cent. But operation is not justifiable merely on account of the smallness of its mortality, and Treves believes that the successes are not so frequent as they are generally supposed or asserted to be. In Keen's 116 cases traced for three months, only 57.8 per cent. were cured, and 12.9 per cent. improved; in 19.9 per cent. the operation failed. Moreover, apart from mere failure to secure replacement, the operation has been followed by neuralgia, sometimes renal, sometimes radiating down the outer side of the leg and into the foot. Up to 1895, in common with other surgeons, Treves regarded operation as the only treatment, but he now considers that it should be resorted to not as the first, but only as the last resort; and he reserves it for cases in which torsion symptoms have occurred (when the sooner operation is done, the better); when patients are to travel beyond the reach of surgical aid; when patients have to work for a living and cannot adjust the apparatus described below, and when all other modes of treatment have failed. It is surprising, Treves says, to see how small the last class will really be; so small indeed that he believes the operation of nephrorrhaphy will soon become one of the rarest in surgery.

When operation is not in question, Treves treats by a month's rest in bed, with careful feeding and attention to the digestive functions, and general massage. This will not fix the kidney, but it will rid the patient of the symptoms. For the rest, he depends upon a special truss which he describes and illustrates. The particular point is that an attempt is made to reproduce the pressure of the fingers by a metallic abdominal pad upon which pressure can be made at two points, by two springs, on the inner and lower borders, so as to press the kidney upward and outward. Since 1895, 300 such trusses have been used with success in 95 per cent. of the author's cases. The apparatus demands careful adjustment, this sometimes requiring several sittings. Usually after one and one-half to two years the apparatus can be dispensed with.

DR. OSLER'S JOKE.

In an address delivered at the commemoration exercises of the Johns Hopkins University on February 22, Dr. William Osler, since 1889 professor of medicine at that university, and for the next four years to be regius professor of medicine at Oxford, signalized his farewell to his colleagues and students by some jocose remarks which have been taken with unexpected seriousness by the press. He spoke first in defence of the rolling stone, of which he may be regarded as a conspicuous living example, having himself (to use his own simile) rolled from Montreal to Philadelphia, and thence to Baltimore, and being about to twirl finally across the sea, and then proceeded to elaborate his old-time witticism regarding the uselessness of men past the so-called prime of life. He had two fixed ideas, he said, the first of which was "the comparative uselessness of men over forty years of age. . . . Take the sum of human achievement in action, in science, in art, in literature—subtract the work of the men above forty, and while we shall miss great treasures, even priceless treasures, we would practically be where we are to-day." To make his point he mentioned a few of the great men of our profession. "In the science and art of medicine there has not been an advance of the first rank which has not been initiated by young, or comparatively young, men. Vesalius, Harvey, Hunter, Bichat, Laennec, Virchow, Lister, Koch—the green years were yet upon their heads when their epoch-making studies were made."

The subtle humor of this statement becomes apparent when we remember that Harvey was born in 1578, and published his work, "Exercitatio de Motu Cordis et sanguinis," in 1628, when he was fifty years old; that Lister was born in 1827, and was close on to fifty years of age when he began to convert the medical world to the principles of antiseptic surgery; and that, while Koch was born in 1843, and was within one year of forty when he discovered the tubercle bacillus, even the least appreciative of his admirers will admit that he has done some good work since 1882. George Washington, on whose birthday Dr. Osler promulgated his belief in infant prodigies, was over forty-three years old when he was appointed commander of the Continental Army, and was fifty-seven when made first president of the United States. Columbus was about forty-six years old when he discovered America. Bacon, Kepler, Shakespeare, Milton, Oliver Cromwell, Robert Fulton, and Morse, all added to the sum of human achievement long after they had passed the dead line of forty years. Osler published his first medical book when he was forty years old, and Dr. George M. Gould, the accomplished editor of *American Medicine*, did not enter the medical ranks until he was full forty years of age.

Dr. Osler's second fixed idea was "the uselessness of men above sixty years of age, and the incalculable benefit it would be in commercial, in political, and in professional life if, as a matter of course, men stopped work at this age." He offered the following scheme of division of a professor's period of activity: "The teacher's life should have three periods—study until twenty-five, investigation until forty, profession until sixty, at which age I would have him retired on a double allowance."

But maybe this portion of the address was not meant for a joke after all. The last paragraph quoted certainly contains the suggestion of a hint to the Oxford House of Convocation that in four years from now (Osler was born fifty-six years ago) the retirement of the regius professor of medicine (on a double allowance) would be the correct thing.

The Size of the Articular Surfaces of the Long Bones as Characteristic of Sex.

Despite assertions to the contrary, Professor Brinton had many arguments on his side, when he declared that apart from the pelvis, there is no guide to the sex among the bones. Dr. Thomas Dwight of Harvard Medical School, who has been making investigations into the matter, confesses that with our present methods (excepting the pelvis, and even this is not always conclusive), in the great majority of cases the expert must form his opinion of the sex of bones from their general appearance, and that comparatively rarely can he speak with any great certainty. He nevertheless thinks that Professor Brinton was somewhat too positive in his statement, and concludes, from a personal study of 400 humeri and femora of white adults, measured with the articular cartilage in place and still fresh, that the heads of the humerus and femur are relatively small in woman. Probably the same may be said of other joints. Dorsey's investigations show that this anthropological law applies also to savage races—or at least to some of them. The number of measurements of male joints smaller than the average female joint, and of female ones larger than the average male is insignificant. In the transverse diameter of the head of the humerus the combined number is only 1.25 per cent., and in the head of the femur only .05 per cent. By rejecting a few aberrant specimens, the overlapping in the curves of both diameters of the humerus is reduced to about 17 per cent., and is limited to joints measuring 45 and 46 mm. vertically and to those measuring 41 and 42 mm. transversely. The head of the femur is somewhat less characteristic, but still very valuable as a guide to sex. It would appear then, that, by careful measurement of the heads of the humerus and femur, with the articular cartilage in place and still fresh, the sex can be discerned in a large number of cases.

The Inspection of Immigrants.

Dr. Allan McLaughlin of the U. S. Public Health and Marine Hospital Service, writes in the *Popular Science Monthly* for February, 1905, on the above subject. State quarantine authorities board ocean liners upon entering New York harbor, and the immigrants are inspected for quarantinable diseases, such as cholera, smallpox, typhus fever, yellow fever, and plague. The immigrant inspectors and a medical officer of the Public Health and Marine Hospital Service then come on board and examine the cabin passengers, and especially the second cabin passengers. The steerage passengers are then taken to the immigrant station, Ellis Island. The medical examination at Ellis Island is most carefully carried out. Two doctors work together in making the first inspection, one looking out for a certain class of defects and the other for a different class. Routine is followed in making this examination, scrutiny beginning at the passenger's feet, before he comes within fifteen feet of the examiner. The scrutiny commences at the feet and travels upwards, and the eyes are the last to be inspected. The examiners must be on the alert for all forms of deception, as every kind of method is practised in order to be passed as sound. When the last alien has passed the doctor, the suspected ones are thoroughly examined, idiots and those suffering with a loathsome or dangerous contagious disease are certified and sent to the board of special inquiry. Minor defects, such as anemia, loss of an eye, poor physique, low stature, etc., are recorded on the alien's card, and he is allowed to go to the registry clerk and immigrant inspector in charge of the manifest, who takes the defect into consideration as contributory evidence, and may or may not send him to the board. The board of special inquiry consists of "three members selected from such of the immigrant officials in the service as the commissioner general of immigration, with the approval of the secretary of commerce and labor, shall designate as qualified to serve on such boards." When the medical certificate states that aliens are suffering from loathsome or dangerous contagious disease, idiocy, epilepsy, or insanity, such certificate is equivalent to exclusion, the board simply applying the legal process necessary for deportation. Aliens certified by the medical officers as suffering from disability likely to make them public charges, are also held for examination before the board of special inquiry. Although in these cases, the board takes into consideration the medical certificate, it has full discretionary powers, and in a great majority of instances the alien is admitted.

Scientific Work of United States Naval Medical Officers.

The opportunities for undertaking scientific work offered to the medical officers of our navy have been greatly widened of late. The accession of territory in tropical countries by our government has opened up new fields of research to medical officers of the navy and army alike. On the Isthmus of Panama, for instance, there is an immense field for research in tropical medicine. The Isthmus and vicinity literally teem with diseases incidental to the tropical zone, and for the next few years American scientific men will be afforded unique facilities for studying such affections. On the Isthmus advantage has already been taken of these opportunities, and Drs. Carpenter, Surgeon U. S. A., and Sutton, Assistant Surgeon U. S. N., have made some interesting investigations, the results of which have been published in the *Journal of the American Medical Association* for December 17 and January 21, and in the Medical Record for January 14. The articles in the former journal dealt solely with dengue fever, an affection extremely common in Central America. Their investigations did not confirm the views held by Professor Harris Graham of Beyrouth, Syria, to the effect that mosquitos are the conveyors of dengue, in the same manner as the insects are the disseminators of malaria and yellow fever. An article by Professor Graham on the subject was published in the Medical Record of February 8, 1902. The article by Assistant Surgeon Sutton in the Medical Record of January 14, 1905,

is a well considered treatise on the diseases of the Isthmian Canal Zone, which plainly shows that there is no lack of material in that region for protracted scientific investigation. Dr. Sutton's views as to the ultimate health conditions of the maligned Isthmus are optimistic, for he is of the opinion that American sanitary methods will render its dwellers no more subject to disease than are the residents of any extreme southern country. Drs. Carpenter and Sutton are deserving of high praise for the meritorious work done by them during the past summer. American naval and military medical officers are now in the position, at least during a portion of their career, of being enabled to study at first hand and under favorable auspices, the mysterious diseases of the tropics, and there is every reason to hope that they will seize the opportunity of adding lustre to their several services and to their country, by discovering the origin of some of these maladies.

News of the Week.

Dr. Emil Mayer, adjunct attending laryngologist to the Mount Sinai Hospital, has been appointed Chief of Clinic in the ear, nose, and throat department of the dispensary of that institution.

A Clinic on Cancer.—At the completion of Dr. L. Duncan Bulkley's special course of lectures on Diseases of the Skin, held at the New York Skin and Cancer Hospital, 19th Street and Second Avenue, New York, Dr. William Seaman Bainbridge, will give a clinical lecture on Cancer, March 29, at 4:15. A number of interesting cases will be shown.

President Harper Operated On.—February 22, Dr. Wm. R. Harper, President of the University of Chicago, was operated upon by Dr. Charles McBurney, of New York, and, according to a bulletin, issued shortly after the operation, and signed by Dr. Frank Billings, a condition of thickening of the posterior wall of the head of the colon and enlargement of the glands of the mesentery was found. The entire removal of the diseased tissue was deemed impossible by the surgeons, and the wound was closed. The bulletin states that "it was the opinion of Dr. McBurney and Dr. Bevan that the disease was carcinoma. It has been decided that President Harper shall be placed upon medical and *x*-ray treatment, with the reasonable hope that the disease may be checked. It is anticipated that President Harper will make a speedy convalescence."

Dr. Osler's Denial.—The absurd statement in the papers that Dr. Osler, in his now celebrated address, advocated the chloroforming of all men who reached the age of sixty, seems to have been taken seriously by some, naturally much to the discomfort of the putative author of the sentiment. He sends a communication to the MEDICAL RECORD requesting a contradiction of the statement that he advised chloroforming men when they had arrived at this age, asserting that there was no such recommendation in his address.

Compulsory Vaccination Is Not Unconstitutional.—The United States Supreme Court has recently decided that compulsory vaccination ordered by local boards of health on authority of State Legislatures is valid because it is for the public good. The constitutional guarantee of personal liberty, the court holds, is not infringed. The case was brought by a man of Cambridge, Mass., who declined to submit to vaccination in an outbreak of smallpox and was fined. He contended the law was contrary to the preamble to the Constitution, its spirit, and to the fourteenth amendment; that vaccination did not protect, and that it was dangerous, sometimes causing permanent injury to health and occasionally death. In delivering the opinion of the court Justice Harlan said the Constitution did not grant to one person or a minority residing in any county and enjoying the benefits of its local government the liberty thus to dominate the majority in such cases. The matter was primarily one of State regulation and did not ordinarily concern the National Government. The liberty secured by the Constitution to every person within its jurisdiction did not mean that each person should be at all times and in all circumstances wholly freed from restraint.

The Spitting Nuisance.—Recently 171 arrests were made of violators of the anti-spitting ordinance in Chicago. It is hoped that these arrests will serve as a deterrent to others from spitting in public halls and public conveyances. In New York twenty-eight spitters, among them an assistant chemist of the Board of Health, were fined in court one day last week. The magistrate of one court has established a schedule of fines—$2 for spitting on the platform of the elevated road, and $3 for defiling the subway. Those who have been locked up all night are discharged without fine.

A New Medical Monthly.—We have received the first number of a new monthly termed *The Georgia Practician*, which comes from Savannah under the editorship of Dr. Martin Cooley. Practical papers, timely editorials and ethical advertising are promised, and the first issue argues well for the future.

Degree of Chemical Engineer.—A course in chemical engineering leading to the degree of chemical engineer has been established by the trustees of Columbia University. The new course will go into operation at the beginning of the next academic year, and is planned to fit men both in chemistry and engineering to assume responsible positions in large industrial and manufacturing establishments.

A New Department at the Sorbonne.—M. Louis Liard, vice-rector of the University of Paris, recently accepted a proposition made by the Municipal Council of Paris which will be of valuable assistance to American students desirous of following special courses provided by the University. Under the directorship of Dr. David Blondel a department for the dissemination of practical and scientific information is to be established for the purpose of aiding strangers desirous of following special courses of study in Paris. In a room in the Sorbonne a permanent secretary will be on hand every day from 10 o'clock to 4 o'clock, provided with the authorizations and written formalities that a stranger frequently consumes a fortnight in obtaining but which are necessary to gain access to the various laboratories, hospitals, clinics, etc. The visitor will first be required to show credentials of identification and will then be supplied gratuitously with all the documents, addresses, directions for getting about, etc., that he may be in need of.

A Dettweiler Foundation.—To honor the memory of the late Dr. Dettweiler, the founder of the Falkenstein Sanatorium and the first people's sanatorium at Ruppertshain, it has been decided to establish an institution bearing his name which shall be a home for physicians who have served in sanatoria for consumptives, and who have become invalidated by disease, accident, or old age. For the collection of funds and the final arrangements a committee has been formed under the patronage of H. R. H. the Princess Friedrich Carl of Hesse. Of the medical men who have signed the appeal for funds we read such names as Besold, the successor to Dettweiler; Professor Kurschmann of Leipzig, Flügge of Breslau, B. Fränkel, von Leyden, and Pannwitz of Berlin, General Dr. von Leuthold, physician to the

Emperor, and Schmidt of Frankfort. Contributions are to be addressed to Grunelius & Co., Bankers, 16 Gr. Gallus Strasse, Frankfort on the Main.

Mortality Statistics of Philadelphia.—For the week ended February 25, there were reported to the Philadelphia Board of Health 579 deaths, as compared with 599 for the previous week, and 693 for the corresponding week of the preceding year. More than one-quarter of the whole number were due to diseases of the lungs: 74 to pneumonia, 18 to bronchopneumonia, 11 to congestion of the lungs, 51 to pulmonary tuberculosis, 1 to hemorrhage from the lungs. Besides, 15 deaths were attributed to diphtheria and membranous croup, 13 to influenza, 7 to chronic bronchitis, 3 to acute bronchitis, 3 to asthma, 1 to pulmonary emphysema. More than one-fifth of the deaths were due to diseases of the heart and blood-vessels: 55 to heart-disease, 27 to apoplexy, 9 to paralysis, 9 to old age, 5 to congenital malformation of the heart, 5 to diseases of arteries, 4 to endocarditis, 4 to angina pectoris, 3 to embolism and thrombosis.

The Ohio State Board of Health Laboratory announces in its last bulletin that in the future it will aid physicians in making the diagnosis of the infectious diseases. This offer is only open to those who are not eligible to the laboratories of the City Boards of Health.

Licking County (Ky.) Medical Society.—At a meeting held February 7, Dr. Garrison of Utica was elected President, and Dr. C. P. King of Newark, Secretary.

The University of Halle, Germany, has conferred upon Dr. Willy Merck, member of the house of E. Merck, Darmstadt, the honorary degree of Doctor of Medicine "in recognition of numerous meritorious contributions looking to the advancement of the therapeutic side of medicine."

Society of Medical Jurisprudence.—Professor Wilhelm Waldeyer of Berlin has been elected an honorary member of this Society.

The Logan County (Ill.) Medical Society.—At the annual meeting of this Society held February 16, at Lincoln, Ill., the following officers were elected: *President,* Maskel Lee of Atlanta; *First Vice-President,* Carl Rembe of Lincoln; *Second Vice-President,* J. H. Butler of Hartsburg; *Secretary,* H. S. Oyler of Lincoln; *Treasurer,* C. C. Montgomery of Lincoln.

Suit Against a Surgeon.—An ungrateful patient has brought suit against a well-known New Haven surgeon for $25,000 damages, alleging that a roll of gauze was left in the abdomen after an operation for appendictis.

Cuspidors for the Rapid Transit Stations.—At a special meeting of the advisory board of the Health Department held last week, the use of cuspidors in the subway and elevated roads was discussed. A suitable form was examined and approved, and it is likely that the roads will be requested to provide a sufficient number of this type. The cuspidors are made of tin, painted white and designed to be attached to the side of a building. That some such provision is urgently needed is shown by the fact that on one day recently thirty-five spitters were arrested and fined.

Hospital News.—*St. Joseph's Mercy Hospital.*—The rebuilding of the St. Joseph's Mercy Hospital of Dubuque, Iowa, has been completed and the new structure, which represents an outlay of $150,000, has been consecrated by Archbishop J. J. Keane.

Montclair Hospital Opened.—The new $30,000 building of the Mountainside Hospital has been formally opened.

New Eye and Ear Hospital.—At a meeting of the board of directors of the Manhattan Eye, Ear and Throat Hospital, held to consider the plans submitted by the building committee for the contemplated hospital on Sixty-first street, running through to Sixty-second street, between Second and Third avenues, it was found that a suitable hospital would cost nearly $200,000 more than had been appropriated for the building. A gift of $25,000 from a recently elected member of the board of directors induced the board to pass a resolution to incur the debt and begin at once with the construction.

Tuberculosis Ward for Brooklyn.—The Health Department's new building in Brooklyn is to have attached to it a tuberculosis ward of the most modern description. It is proposed to build a one story structure, tiled throughout, without a particle of wood or other material to harbor germs. The tuberculosis ward will be attached to the main building, which will be used for the business offices of the department and fitted for scientific experiments. The new building is to be erected in Flatbush avenue near Fulton street, at a cost of $200,000, and it is expected that it will be completed within eighteen months.

Cincinnati Hospital Annual Report.—Supt. Fahrenbatch has submitted his annual report to the Board of Public Service. He makes a plea for additional buildings at the branch hospital for tuberculosis. The present number of patients, 113, is 43 more than the normal capacity. The main hospital treated nearly 2,000 more patients than in 1903. The gross cost per patient per day during 1903 was $0.9427, and during 1904 it was $0.8877, "which is far below any first-class hospital in the United States or Canada." The daily average number of patients during the past year was 575; deaths during year, 809; total number treated, 9,234; total receipts, $216,603.96; expenses, $220,246.36; deficit carried to 1905, $3,642.40; number of applicants for position as nurse, 214; number of nurses, 77.

Appointment of Medical and Surgical Staff at Dunning, Illinois.—The following appointments were made by President Brundage at a recent meeting of the County Board, for the County Institutions at Dunning: Drs. John B. Murphy, Hugh T. Patrick, J. Rawson Pennington, Charles S. Williamson, Frank Billings, Wm. A. Evans, E. J. Farnum, Alice Hamilton, Arnold C. Klebs and M. McPherson Linnell.

The Manhattan Maternity Hospital and Dispensary, at 327 East Sixtieth street, was opened last week. The new institution will include a training school for nurses and eight student-physicians can be accommodated in the building. There will be a large outdoor department, connected with the dispensary. The building is square, of five stories and basement, and built of brick with a white enamel finish. On the main floor are the dispensary, the examining and admitting rooms, an office and superintendent's reception room, with the students' dormitory and dining room. On the floor above are the wards, accommodating eighteen patients, and the nurseries for both the ward and private patient babies. The ward patients' dining room is also on this floor. On the fourth floor at one side is the operating room and amphitheatre, with seats extending up into the top story. On the top floor are the superintendent's rooms and a private dining room, nurses' dining room, the house kitchen, and big supply room.

A New Cancer Hospital is to be established in this city. A hearing was given the organizers a few days ago by three of the Commissioners of the State Board of Charities. The Board offered no objection to approving a certificate of incorporation for such an institution, provided it was assured that there was enough money to run it for a year.

New Cincinnati Hospital.—Samuel Hannaford & Sons have been appointed architects for the new Cincinnati Hospital, and Dr. C. R. Holmes has been appointed consulting physician for the construction of the same by the Board of Public Service.

Annual Report of St. Francis' Hospital, Evanston, Illinois.—The annual report of this institution states, among other things, that during the year 1904 there were treated 212 cases of various affections, 23 of which were cases of appendicitis.

Obituary Notes..—Dr. JOHN HERBERT CLAIBORNE died at his home in Petersburg, Va., February 24, after a brief illness. He was a graduate of the Medical Department of the University of Virginia in the class of 1849. In June, 1864, when Gen. Lee's army occupied Petersburg, Dr. Claiborne was senior surgeon of the post and chief surgeon of all the military hospitals in Petersburg. He was ex-president of the Medical Society of Virginia, a fellow of the Southern Surgical and Gynecological Association, of the American Medical Association, of the American Health Association, and of the Boston Gynecological Association. He leaves a widow and several children, among whom is Dr. John Herbert Claiborne, Jr., of New York.

Dr. MORTIMER WRIGHT SHAW of this city died of pneumonia at Middletown, N. Y., on February 22, at the age of 37 years. He was a graduate of the Long Island College Hospital in the class of 1892.

Dr. JAMES E. CRISFIELD of Dansville, N. Y., died February 24, at Jacksonville, Fla. Dr. Crisfield was the oldest practicing physician in Livingston County. He was graduated from the College of Physicians and Surgeons in this city in the class of 1873.

Dr. FRANCIS NORTON PHELAN of Duluth, Minn., died on February 11, at the age of 43 years. He was born in Fond du Lac, Wis., and was graduated from the Medical Department of Wooster University, Cleveland, Ohio, in the class of 1884.

Dr. ALBERT BENJAMIN PRESCOTT, Director of Chemical Laboratories of the University of Michigan, Professor of Organic Chemistry, Dean of the School of Pharmacy, and the oldest professor in the university in point of years and service, died at Ann Arbor February 25, aged seventy-two. He formerly was President of the American Association for the Advancement of Science and the American Pharmaceutical Association.

CHARLES DENNIN, a well-known apothecary of Brooklyn, died of pneumonia on February 19, at the age of 65 years. During the civil war he served as apothecary on the ship Ocean Queen, presented to the Government by Commodore Vanderbilt. He was a member of the Sanitary Commission during the war and for some time chief apothecary of Bellevue Hospital. In 1865 he established his drug store in South Brooklyn. He was one of the founders, and for several years the treasurer, of the Brooklyn College of Pharmacy. He was also a charter member of the Kings County Pharmaceutical Society.

Dr. D. W. DUNDORE died at Womelsdorf, Pa., on February 23, at the age of 48 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1879.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SCHOOL HYGIENE [illegible] SYMPTOMS [illegible] SWEATING AND SWEATING—PHYSICAL DEGENERATION—THE LATE LUTHER HOLDEN—COLLEGE OF SURGEONS, PROPOSED NEW SCHOOL.

LONDON, February 10, 1905.

In view of the International Congress on School Hygiene, to be held in London in 1907, the educationalists, taking time by the forelock, have been holding a conference here this week, which opened on Tuesday and is to conclude this evening. Delegates have attended from about 170 societies and educational authorities, including eleven universities and the Royal College of Physicians and Surgeons. Similar conferences are, it was stated, being held in the chief towns of various countries.

The meetings here have been held at the University of London, and its Principal, Sir A. W. Rücker, gave the presidential address, in which he argued that some science should be taught to all children in secondary schools and the principles of hygiene should be included under that head. The University, he said, sympathized with every effort to give a tincture of knowledge of hygiene to all children, whether in public schools or not, and he hoped the conference would succeed in its endeavor to secure the reasonable cultivation of the subject and would insist that all to whom the care of young lives were entrusted should have learned the main outlines of the science.

Sir Lauder Brunton presided on Wednesday morning, when the importance to children of physical development, fresh air, good light, wholesome food, sleep, and ten other subjects were discussed. In the afternoon Lord Reay presided and expressed a wish to see school and home teachers and parents brought into more or less intimate relations. Dr. Chalmers showed diagrams to illustrate the relations between dull children and overcrowded tenements, plus underfeeding and malnutrition. Dr. Kerr, medical officer of the County Council, declared school methods required to be rewritten and the final chapters must fall to the school doctor and the medical psychologist. Ill nutrition depended on want not merely of food, but of clothing, cleanliness, and air. Dr. Newsholme and others commented on school nurses, the propriety of changing boots for slippers on reaching school, and details as to care for the children's health.

Resolutions were adopted urging the Board of Education to appoint as inspectors (some women as well as men) those who are specialists in school hygiene. It was also agreed that no child should undergo instruction in classes under 6 years of age, and that there should be regular medical inspection of the children in all schools.

Yesterday the morning meeting was occupied with school buildings, apparatus, and equipment. In the afternoon there was a lengthy discussion on Sanitary Inspection of Schools, and eventually a resolution was carried that the control of schools from a sanitary point of view be referred to the Council of the Royal Sanitary Institute for consideration, with a view of such representations being made to the proper authorities as that Council may deem fit.

Some rather curious cases were exhibited at the Clinical Society's last meeting. One was of extensive syphilitic necrosis of the skull, causing intracranial abscess but with no cerebral symptoms. Four years after treatment for primary syphilis the man had rupia, joint pains, iritis, etc., and was again treated. He then remained free for 10 years, when (February, 1904) a lump formed on the vertex, followed by sloughing of scalp, and then by necrosis beneath until the cerebral pulsations appeared, but the man was able to go on with his work as a letter carrier and had no headache, giddiness, or other cerebral symptoms. Admitted to hospital, the dead bone was removed by trephining, and a large subcranial collection of pus found between the skull and the dura mater.

Mr. Hutchinson, Jr., who showed the case, said it appeared originally to be a periosteal gumma which had softened, and could be scooped out with the finger.

A very different exhibit was brought by Dr. P. Weber, viz., a case of localized flushing and sweating on eating, which, together with "striæ patellares," followed appendicitis ten years ago. The patient was shown in October, 1897, but the symptoms still persist. When he begins to chew solids a patch of redness appears on the *left* cheek and the skin sweats. When this is at its maximum a smaller, less marked patch may appear in front of the *right* ear. After ceasing to chew, the symptoms gradually subside. Movements of the jaw as in mastication call forth the phenomena to a less degree than chewing solids. So does holding vinegar and water in the mouth. Swallowing has not the effect. The striæ patellares are well marked, resembling the lineæ albicantes gravidarum and it was suggested were caused by the fixed position of the knees

when suffering from appendicitis. Dr. Weber thought another factor was the rapidity of the patient's growth, and asked what effect long illness had on lineæ gravidarum. On this Sir D. Duckworth referred to a case he published in the *Transactions,* in which lineæ followed typhoid, but he added, such lines appeared in robust health and he saw no reason to call in any factor other than pressure. Mr. McGavin said if Dr. Weber's explanation held, the lines ought often to be seen over tuberculous ankylosed joints, but as to that Dr. Weber held that a febrile disease gravely affecting nutrition differed from a local joint disease.

Sir Wm. Church, President Royal College of Physicians, took the chair at a meeting to urge the advantages of military or naval training as a remedy or preventive of physical degeneration. Sir William spoke of the importance of the subject in view of the unsatisfactory condition of the mass of our population.

Col. Duke, in an interesting address, urged that the government should go back to first principles and require every boy while at school to be so trained and developed as to be able, if need be, at a later period to help in the defense of his country. Comparing the habits of the Jews and others, he declared that 98 per cent. of Jewish mothers nursed their children, but 96 per cent. of British mothers either would not or could not. This abandonment of Nature's law had a most evil effect on the population. Mothers should be taught that nature and true patriotism required that their children should be properly fed and properly trained to develop the quality of the race.

A venerable and venerated teacher has passed away in Luther Holden, who died on Monday, in his ninetieth year. He was apprenticed to Stanley of St. Bartholomew's Hospital in the old days when privileges attached to such apprenticeship. But it was long before he became a member of the hospital staff. In fact he was elected assistant surgeon in 1850, but five years later he became full surgeon through several retirements. But long years before these dates he had established himself as one of the most successful and popular of teachers of anatomy and its relations to surgery. In the early forties he was demonstrator at the hospital school and continued to hold that post until 1859, when he became join lecturer with Skey. His Manual of Dissection, first issued in 1851, was the popular textbook, but it was his beautiful work on "Human Osteology," the first edition of which appeared in 1855, that established his great reputation beyond his own school, where of course it was well known and appreciated. The fine illustrations were his own drawing, and on the bones the attachments of the muscles were all marked. This was a new departure in anatomical teaching and original with Holden. So striking a method was of course pronounced at first too easy by some teachers, especially by those who were enamored of the minutiæ of dissection. But the "pretty picture book" was speedily imitated and is now largely followed, though few if any of its successors have equaled Holden's colored plates. In 1876 appeared his "Medical and Surgical Landmarks," which, however, had previously been printed in instalments in the *St. Bartholomew's Hospital Reports,* 1866 and 1870.

Holden became consulting surgeon to the hospital in 1881 and retired the year in which he delivered the Hunterian oration, at the Royal College of Surgeons, of which he was president in 1879, having previously held all the minor offices. He was twice married and leaves a widow but no children. In old age he made voyages to the Cape and Australia; in 1898 he was entertained by the profession in the Transvaal. On his retirement he went to live in Suffolk, of which county he was a magistrate, but came to town at times to visit friends or the college where I last met him, and now retain a pleasant memory of that interview.

Yesterday at the Council meeting of the Royal College of Surgeons a vote of condolence was adopted with the widow of the late Mr. Luther Holden and of appreciation of the services of the late past-President.

The Council afterwards discussed the proposal to establish a teaching school, and appointed a committee to consider and report upon the practicability of the institution by the college of a school for teaching the early and intermediate subjects of the curriculum and of advanced pathology. In reply to an invitation from the President of the International Medical Congress, it was decided to send a representative.

Government Physicians.—One of the Swiss cantons, Zurich, is about to try, according to report, the experiment, decidedly more interesting than hopeful, of creating a medical service fund by taxing every citizen 86 cents a year, and with this money employing something like fifty physicians, who will respond to all calls without further remuneration. There is little likelihood that the experiment will be a success, however, for the practical difficulties in carrying out such a plan could hardly be overcome.—*The Times.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, Feb. 23, 1905.

Eye Strain.—Myles Standish points out the possible combination of ocular abnormalities which would make a heavy drain upon the nervous reserve force, so necessary to every one in times of stress and depression. Nearly every individual has some ocular defect, many being unaware of this fact, until beginning presbyopia emphasizes the infirmity. The effects of eye strain are legion. The man, and not the eyes, is responsible. In many cases of nervous dyspepsia, for example, the troublesome symptoms have disappeared after a correction of the error of refraction. In children and youth it is certain that epileptiform convulsions, indistinguishable from those of true epilepsy, have been absolutely cured by the correction of the error of refraction or the muscular imbalance.

Allen Greenwood speaks of the inattention of children and apparent backwardness, which is due to eye strain. This condition is not recognized as it should be for two reasons—the desire of parents to avoid the use of glasses by the child, and the fact that such children have a normal acuity of vision. He believes that teachers should be trained to observe the symptoms of eye strain, as well as to test the visual acuity. Many symptoms are mentioned, among which are the following: Backwardness in children otherwise bright and active, inattention during study hour, frequent rubbing of the eyes or pressing them shut with the hands to rest the tired ciliary muscles, scowling, blinking or pinching the lids together when studying, and twitching of the orbicularis muscles. The child's eyelids are often red and the edges covered with scales. The eyes are hot and painful. Often it complains of increasing headache. The oculist and family physician should work together. The correction of adenoids, nasal obstructions, anemias, and other abnormalities would often obviate the necessity of wearing glasses for a slight error of refraction.

Henry W. Kilburn has observed a number of cases which have convinced him that refractive error or vertical heterophoria may in certain cases be a predisposing cause of scoliosis. He believes that any refractive error or any condition of muscular imbalance which causes a growing child to lean too far forward over the desk, or which causes a tilting of the head to one side, may induce a lateral curvature. An oblique astigmatic axis may also be a cause of this deformity. Eye strain has undoubtedly played a rôle in a number of cases of torticollis.

Henry H. Haskell calls attention to certain reflex prenomena of nasal origin, most of which resemble the ordinary symptoms of eye strain. Pressure-contact in the nose may cause symptoms like those of eye strain. On close examination in these cases, however, certain anomalous features will be found, different from those due to faulty refraction alone. Moreover, it must be remembered that a faulty nose may also cause real symptoms of eye strain through its effect upon the refraction. Headache is the most constant symptom of nasal trouble. This is generally unilateral, and the pain becomes worse, if anything, when the patient lies down. Morning headache, present on waking, is almost invariably of nasal origin, due to congestion of the turbinate. In these cases the effect of an operation on the nose on the refraction, is very striking.

Edwin E. Jack mentions several conditions in which eye strain should be suspected. As to headache, when the pain comes on repeatedly, during or immediately after the near use of the eyes, the inference is direct. Headaches which are around or back of the eyes, frontal and occipital, are especially suggestive. Local suggestions of strain come from eyes which have been congested in use or that have a chronic conjunctivitis and inflammation of the lid margins with crust formation. Many people cannot go to the theater, ride in cars, or go shopping, without headache, vertigo, confusion or severe prostration following. Many of these cases are explained by faulty refractive or muscular conditions. It is the lesser degrees of error that cause the most trouble. Greater degrees of error cause poor vision, and poor vision maintained by no effort causes no strain.

Fred M. Spalding explains various difficulties encountered in the prescription of glasses. The time that it takes one to become accustomed to wearing glasses varies considerably, according to the age of the patient. It is always wise as a matter of routine to inform patients that in all probability their glasses will not feel comfortable at first. A common cause which tends to prolong the period of adaptation is a faulty balance of the external ocular muscles. Other patients who find it difficult to get accustomed to glasses are those who show a marked difference in the refractive error of the two eyes. Another condition which often gives rise to trouble is spasm of the accommodation. Glasses themselves often have the effect of producing changes in the appearance of objects. The prismatic effect

of looking obliquely through glasses is also rather disturbing to the novice. A special lens called the toric lens has been designed to correct this difficulty.

New York Medical Journal, February 25, 1905.

Myocardial Degeneration.—A. E. Roussel includes under this heading the following varieties: (1) fibroid degeneration; (2) fatty degeneration; (3) brown atrophy, a common change in that portion of the heart muscle secondary to valvular affections. It is generally present also in the old and in those who have died from wasting diseases. Rarer forms are amyloid, hyaline (in prolonged fevers), and calcareous. These latter three possess no clinical interest. The symptomatology of the general condition is detailed. A parenchymatous form is also met with in the infectious diseases, especially when they are protracted and accompanied by high temperatures. Perfect recovery from this form is common enough, but the myocardial degeneration, even where not recognized, is the cause of many sudden deaths. As to treatment, rest in bed, easily digested food (largely nitrogenous), and attention to the bowels are of primary importance. Occasional purging with high rectal irrigation is also of service. The most valuable drugs are iron, strychnine, and arsenic. Digitalis is to be avoided. Oxygen is of service. In cases where there are evidences of increased arterial tension, the nitrites are of benefit. When the contrary is the case, small doses of atropine may be tried with good results. Aromatic stimulants are, as a rule, better suited for syncopal attacks than whiskey or brandy, but the use of light wines is often beneficial. The patient is sensitive even to proper clothing and warm water for bathing. For restlessness, small doses of heroine guarded by atropine are useful. In Cheyne-Stokes breathing, strychnine, hypodermically, and oxygen may be administered. In attacks of angina, nitrate of amyl and nitrogylcerin may be given hypodermically. As the patient improves, graduated exercise, either by the Oertel or Schott treatment, should be begun.

Intestinal Perforation.—H. M. Taylor reviews the statistics of this accident. There are probably 15,000 such cases annually in the United States. The best statistics show a recovery percentage of fifty. The crucial point is that of early diagnosis. Cases are typical and atypical. If the patient has done well up to a certain time, and while having an action of the bowels is taken with sharp continued pain, tenderness, and muscular rigidity; perhaps with chill, reduced temperature, increased pulse rate, and vomiting, symptoms of shock, we have a chain of evidence pointing to perforation, as closely linked as that upon which we commonly have to rely in most acute peritoneal infections. On the other hand, it is easy to see how such symptoms may be masked if the patient is delirious, if there is abdominal distension and gastroenteric disorder, and if there have been daily marked variations in pulse and temperature. The symptoms of intestinal bleeding may at first simulate those of perforation, and the two conditions may coexist. In view of present day surgical methods the author thinks that we ought to have from 50 to 60 per cent. of recoveries from operation.

Electricity in Otology.—J. J. Richardson believes that electricity in otological practice will stimulate weak muscles, relieve pain either by direct action of the current or by the cataphoretic application of anesthetics, stimulate absorption of inflammatory exudates, overcome stenosis or even complete strictures, and at times revive nervous activity. He describes the forms of apparatus he employs, and finds electricity of service in tinnitus aurum, and in dissolving strictures of the Eustachian tube. Not much can be expected in cases of deafness of either tympanic or labyrinthine origin. Hysterical deafness, like hysterical aphonia, is best treated by the faradaic current. Pruritus of the auricular canal, which is so distressing at times, is often benefited by this form of treatment. In neuralgic otalgia the interrupted current is very efficacious, when applied by means of an intraauricular electrode. Cocaine applied to the ear acts very incompletely, but its anesthetic effect may be aided by the action of the constant current. This cataphoric process is utilized in producing anesthesia of the tympanic membrane and external canal for slight operative procedures. The auricular canal is filled with a 10 per cent. solution of cocaine and a mild current allowed to pass for five to ten minutes when anesthesia ensues.

Medical News, February 25, 1905.

Observations Upon the Morphology and Classification of the Mycobacterium (Bacillus) Tuberculosis.—C. F. Craig has studied the morphology of the tubercle bacillus and discusses its variations in length, breadth, contour and staining power. Common departures from the classical type are: (1) The streptococcic form, so named because in stained specimens the appearance is that of chain cocci, due to interruption of the stain; (2) the clubbed form, in which one end of the bacillus is very large and takes the stain deeply; (3) the budding form, found in two-thirds of the specimens examined. This form consists of a rather long rod, at one or more portions of which there occurs a distinct enlargement or knob projecting laterally. It is undoubtedly the first stage of (4) the branching form found frequently in patients returning from the tropics. In this form the bud expands into a very short branch. The organisms showing branches are always longer than those surrounding them. Craig believes that the *B. tuberculosis* belongs to the actinomyces, and is not a true bacillus while it is pleomorphous. It answers in every way to this classification, as it presents true branching, the club formation and mycelial formation. The author does not discuss the clinical significance of these various forms, but promises a further contribution along these lines.

Sprains of the Knee and Ankle Joints.—If the case is seen early, J. T. Wilson advises wrapping the knee in flannel cloths saturated with water as hot as can be borne and covered with rubber tissue or similar substance. If there is a simple contusion, a stretching of the tissues without laceration, a gentle massage for ten or fifteen minutes, followed by the Cotterell dressing, *e.g.* strapping the joints with strips of adhesive plaster firmly applied longitudinally, beginning six or eight inches above and extending as far below the knee, overlapping each other and surrounded by a well-fitting roller bandage, is the most effective and satisfactory treatment. In more severe cases the point should be kept at absolute rest, the effusion being aspirated under strictly antiseptic precautions. As the condition improves the dressing may be removed, gentle massage practiced, and the dressing snugly reapplied. After ten to fourteen days, if there is no pain of motion, the patient should begin to walk about some each day. The same general principles apply to injuries of the ankle joint. The author gives in the course of his article very minute and accurate descriptions of the dressings and apparatus he employs, and full directions for their application.

American Medicine, February 25, 1905.

Relation of Pathology to Other Sciences.—J. Orth discusses this subject at length, showing the close relation which exists between pathology and the natural sciences. It is not only the receiver which makes practical use of scientific discoveries, but also the producer which by its own effort, and through independent performances, furthers science. The modern development of bacteriology, the determination and elaboration of exact methods of investigation, the morphology and biology of bacteria have been largely due to the efforts of physicians and pathologists. However, the greatest progress of pathology in the immediate future will be along the lines of chemistry. In all directions pathologists have united with chemists to further the study of the chemistry of proteids. Physicians and pathologists have furthered the knowledge of precipitins, agglutinins and lysins of various sorts, not only in their practical but also in their purely scientific relations, and have begun to study these substances along different lines. Orth asserts that although pathology must necessarily be in uninterrupted relation to medical art, still it remains first of all an independent physical science, which in its three branches, pathologic anatomy, physiology and chemistry, stands on an equal plane with normal anatomy and physiology and physiological chemistry; with them and etiology forming the scientific basis for practical medicine.

Purgation Before and After Operation.—I. S. Stone discusses this subject at length; he asserts excessive purgation should be restricted because it is enervating to the general system. It produces great irritation to the mucous lining of the bowel. It may add to the danger of ileus and paresis. Purgatives have very little effect in limiting the amount of extraperitoneal exudate and fluids. Instead of calomel and saline purgation, bland evacuants such as castor-oil should be used before abdominal section. The use of suitable bland non-fermentive foods is desirable until just before operation in weak patients. After operation limit peristalsis; give only small quantities of food and drink by mouth. Rarely give opium. Enemas should be administered to relieve distension and cause peristalsis in downward direction, after normal peristalsis laxatives should be given as required.

Cystoscopy.—H. D. Furniss speaks of the advantages of the use of the cystoscope in the definite and accurate diagnosis of diseases of the bladder, ureters, the kidneys, and their pelves. In hematuria and pyuria, cystoscopy, and ureter catheterization, will reveal the source of the trouble, and often the causative factor can be definitely determined through these means of examination alone. He enumerates the advantges of the different forms of cystoscopes—the Kelly-Pawlick, with its modification in the instrument carrying a small incandescent lamp at the bladder end—the one of Cullen carrying this light on a beak; the air-dilating cystoscopes, or those in which dilation of the

bladder is produced by the forcible introduction of air into the bladder; and the different forms of water-dilating instruments, catheterizing and noncatheterizing, and of the direct view and the prism view instruments. He prefers the water-dilating instrument with the direct view, in which the telescope with the double catheter barrels are removable. In using this instrument with a cold lamp, on the removal of the telescope, a Cullen instrument is produced; a telescope with a prism set of lenses can be used, giving an instrument similar to the Nitze; or, a window can be introduced in the ocular end of the instrument, and air introduced under pressure, giving an air-dilating instrument. He advocates more general use of cystoscopy and ureter catheterization, but not indiscriminately.

Suspected Embolism of Superior Mesenteric Artery.—James A. Nydegger furnishes the clinical history and autopsy of a case with comments. The patient was convalescent from an operation for tuberculosis of the perineum when he was suddenly seized with pain in the hypochondrium, accompanied by vomiting and thirst. At first the condition simulated gallstone colic. Death occurred in eighteen hours from the onset. Autopsy showed the part of the small intestines and colon supplied by the superior mesenteric artery in the incipient stage of gangrene. No embolism was found. The chief symptoms were great thirst, rapid weak pulse and vomiting of dark coffee-colored fluid. Abdominal distension was noted toward the end. Particular stress is laid on the symptom of thirst, which is not mentioned in cases reported by Osler and Watson. Attention is also called to the short duration of illness before death.

The Journal of the American Medical Association, February 25, 1905.

Typhoid Fever.—William Royal Stokes has studied the etiology of several epidemics of typhoid. In the first two reported the infection was traced to springs, and in the second of these all other possibilities were fairly excluded. Another epidemic was clearly traced to the milk supply and has already been reported by Fulton. A rather striking fact in this connection was the infection of a number of female factory employes who were supplied a dairy lunch, while the men, not supplied, entirely escaped. A small outbreak which occurred in a suburban community is noteworthy on account of the long periods of incubation, 23 and 28 days in two cases. The last epidemic reported occurred among students in a college, and was traced to a student returning from Christmas vacation at home. The sewage was infected from this case and the seepage from the sewer infected the spring. Only those who drank this water took the disease, and the epidemic ceased as soon as its use was discontinued. In all these epidemics the water or the milk supply was thoroughly examined bacteriologically, and the findings corresponded with the result, the colon bacillus being present in all the infected fluids. The article shows the value of thorough sanitary surveys in typhoid epidemics.

Multiple Neuritis.—Wharton Sinkler, after discussing the various causes of multiple neuritis, such as alcohal—by far the most frequent—coal-gas poisoning, carbon disulphide, metallic poisons, white lead, copper, phosphorus, mercury, etc., calls attention to the use of patent medicines containing alcohol as a possibility. He reports a case due to the use of arsenic as a medicine in a child treated for chorea, and refers also to the epidemic traced to arsenic in the glucose used for making beer, which was reported in England in 1899. He also refers to infectious diseases as a cause of this condition, and reports four cases from an apparently hitherto unrecorded cause, namely, puerperal septicemia. In conclusion he reports a case of unknown origin, one of a class that is rather difficult to diagnose from Landry's disease, except by the later involvement of the bulb in the latter affection.

Hemiplegia.—T. H. Weisenburg has studied 160 cases of hemiplegia in the Philadelphia General Hospital with special reference to heredity, pain, muscular atrophies, respiration, edema and the arthropathies, vasomotor disturbances and hemichorea. In 109 cases where the facts could be ascertained heredity was present in 14 and strongly manifested in 5 cases. In 17 there was prehemiplegic pain, which is accounted for as possibly due, in persistent cases, to cerebral congestion or actual small hemorrhage in the sensory pathway. Twenty-seven had post-hemiplegic pains. In 30 cases there was either total or partial anesthesia, and in the majority some pains. It appears that pain in hemiplegia is most likely to occur in cases with sensory changes. Weinsenburg confirms Hughling Jackson's observation of the greater expansion of the upper portion of the chest on the paralyzed side during quiet respiration, but he also found, and Dr. Spiller confirmed the observation, that at the end of ordinary or quiet respiration the chest retracted more than on the paralyzed side, thus showing greater power of expelling the air on the sound side and actual weakening of the lung of the affected side with diminished respiratory movements. He reports a case of intense edema on the paralyzed side; in two other cases there was edema of the paralyzed hand. Among vasomotor disturbances he notices the rare occurrence of anidrosis in one of his patients, Weisenburg considers Bonhoeffer's explanation of a lesion in the extension of the anterior cerebellar peduncle into the subcortical ganglia as the most probable theory concerning post-hemiplegic chorea. In every one of his 160 cases there was some muscular atrophy, more marked as the paralysis was marked, affecting the upper more than the lower limb, and, in the majority of cases, accompanied with sensory symptoms. In a large number considerable atrophy was also observed on the so-called sound side. Arthropathies as described by Marie occur in most cases of hemiplegia. They affect mostly the shoulder joint, but with marked contractures other joints also may be involved. Weisenburg thinks the cause is probably the forced immobility plus the pulling on the articulations and tendons by the weight of the paralyzed member. Lesions of cells of the anterior horns are not common in hemiplegia, and, in the cases examined, no pathological changes were found here. He notes, however, one or two peculiar cases, and in two or three of his patients there was painless arthritic conditions suggesting somewhat the arthropathies of chronic spinal disease.

Fat Embolism of the Lung after Fractures.—F. Gregory Connell remarks on the rarity of American literature on this subject. He reports two cases. In practically all fractures, he says, there is more or less fat embolism, according as there is comminution, rough handling, etc. It may also follow orthopedic operations, surgical procedures, inflammations, fatty liver, etc., and the most striking feature is the preliminary period of euphoria, while the most important clinical symptom is the presence of fat in the urine or sputum. Later respiratory and cerebral symptoms may appear at any time up to the fifteenth day. The condition is frequently overlooked or confused with shock, septicemia, pulmonary embolism, effects of anesthetics, etc. As we do not know its frequency its prognosis is uncertain. It probably occurs in a mild form after a large proportion of fractures, and is unrecognized. The only treatment that is practically available is judicious heart stimulation.

Dangers from Indiscriminate Use of Cathartics in Acute Intestinal Conditions.—M. L. Harris states that physicians often fall into the error of prescribing cathartics in every case in which there is interference with normal bowel action without considering the cause of the condition. He calls attention to the danger of giving cathartics in cases in which there is mechanical closure of the lumen of the bowel, such as occurs in strangulated hernia, or in strangulation by reason of loop of bowel becoming caught in an omental or mesenteric opening. He states that if cathartics are given in these conditions, the contents of the intestine above the obstruction are turned back and forth, and not being able to pass the obstruction, are forced back into the stomach, thus giving rise to the foul, offensive vomiting so characteristic of the condition. In intussusception the chief effect of cathartics is to augment the congestion and swelling and thereby lead earlier to complete obstruction and sloughing. Dr. Harris reports a case of sigmoiditis in which a cathartic produced bloody stools. He operated, thinking that there might possibly be an intussusception, but found only a sigmoiditis. Dr. Harris protests against the indiscriminate administration of cathartics in acute conditions in the abdomen, and emphasizes the importance of physiological rest of the intestine. He advises early operation in all cases of mechanical obstruction.

A Case of Arthritis Deformans in Which Large Doses of Arsenic Were Taken.—Duncan L. Alexander reports the case of a farmer, aged 24, who was admitted to the medical clinic of the University Hospital, complaining of dull, heavy pain with stiffness and deformity of many joints. The patient's family and previous history was negative; he denied venereal disease. The present disease began six years previously with a dull, heavy pain, swelling, and grating on movement of the left knee. The same condition manifested itself in the left hip, left elbow and wrist in rapid succession. Four years later the temporomaxillary joints became involved, and one year later the right hand, elbow, hip, knee and ankle became affected. There was pigmentation of the skin and at times a feeling of uncomfortable warmth of the upper part of the body, followed by perspiration or coldness. The patient was able to limp about with the aid of crutches, and when lying down was unable to raise the lower extremities. The treatment consisted of applications of oil of gaultheria to the joints, small doses of salol and phenacetin internally for the pain, and Fowler's solution in increasing doses. The patient improved under this treatment and was discharged from the hospital, but returned two years later, complaining of heavy pain in the joints, twitching of the muscles and

general stiffness. While he was taking Fowler's solution the pigmentation of the skin increased, and this was especially noticeable as the dose of Fowler's solution was between 10 and 16 drops three times a day. Dosage above 16 drops caused swelling of the lids, suffusion of the conjunctiva, and a tendency to diarrhea. The patient developed a severe neuritis of the internal crural and inguinal nerves, but it is doubtful whether or not this is due to the arsenic, which he took for a period of nearly two years.

The Lancet, February 8, 1905.

Sabouraud's Method of Ringworm Treatment.—J. L. Bunch notes that antiseptics in this disease are variable in their result, and are especially unsatisfactory when once the fungus has invaded the hair of the scalp. No antiseptic can penetrate the hair follicle to a greater depth than one millimeter. The hair of a child, however, is implanted in the skin to a depth of four millimeters, and the parasite of ringworm involves the hair root down to the terminal enlargement of the bulb. The ideal agent to cure the disease would therefore be one capable of inhibiting for a time the function of the papilla from which the hair grows. Such an agent is found in radiotherapy. The method is painless, time required short, and the diseased hairs fall out at a definite interval, and are replaced after a certain time by a growth of healthy hair. Bunch describes the apparatus used in the clinic of Sabouraud, and finds that by means of the various instruments employed by the latter, the dose, so to speak, of radioactivity can be definitely estimated. A scalp thus treated shows no changes for a week, but then a slight erythema appears, and at the end of another week the hairs fall out and have a look as if they had been scorched. The growth of the new hairs is slow. The action of the rays is not fatal to the parasite, for cultures made from remnants of hairs in process of expulsion are still active. Reinfection of the scalp is consequently easy. As to the safety of the method, it may be said that there have been but six instances of *x*-ray dermatitis in two thousand applications. The average time of treatment is three months and a half, that is—a case is cured in that time. Results thus far attained are most encouraging.

Traumatic Lumbago.—The histories of six cases are given by F. Romer. By the term traumatic lumbago he means a condition of pain and stiffness in the lumbar region, caused by injury, long after the immediate and acute effect has passed away. Pain is generally referred to one definite spot, though the whole region may be tender. The lumbar muscles are generally somewhat wasted, while on the affected side they are generally rigid and contracted. Care must be taken to exclude spinal caries. Treatment aims to stretch the contracted muscles and to rupture the adhesions which are deemed to be present. General anesthesia is required to secure freedom from pain, insure complete muscular relaxation, and absolute freedom in manipulation. Romer describes in detail the various manipulations required. The after-treatment is directed towards the maintenance of movement, for which purpose it is advisable to have the lumbar and gluteal muscles skilfully shampooed within six hours of the operation. In the course of a few days exercises graduated by means of pulleys and weights should be commenced, in addition to rubbing. Later, swimming is a most healthful exercise.

Acute Hemorrhagic Pancreatitis; Operation; Recovery.—The case is described by T. C. L. Jones, whose patient was a woman of twenty-eight years with signs of intestinal obstruction. Her symptoms calling for abdominal exploration, this was done, and three pints of bright blood mixed with serum were found in the peritoneal cavity. Search through the viscera showed the pancreas about three times its normal size, discolored, edematous, and in places hemorrhagic. There was no bleeding from the organ at the time of operation. The organ was packed around with gauze and then incised longitudinally. The impression was given to the entering finger of a dilated space, which was also packed. Bleeding was at all stages of the operation easily controlled, and the patient did well afterwards. Packing was removed in thirty-six hours, when a discharge of clear fluid began and continued. This was pancreatic juice, and it soon caused trouble at the upper part of the incision, the lower two-thirds of the wound healing by first intention. Apart from an abscess which formed in the abdominal wall, owing, perhaps, to the tube being taken out a little too soon, the patient made an uninterrupted recovery, leaving operation fat-containing food was withheld as much as the hospital quite well, with the wound firmly healed, ten weeks after operation. For the first three weeks after the possible. Her urine was most carefully examined on two separate occasions, and nothing in the nature of the crystals described by Cammidge could be obtained. A motion which was passed naturally on the day following the operation was apparently normal, and no history of any previous alteration in the appearance of her evacuations could be elicited.

British Medical Journal, February 11 *and* 18, 1905.

Pathology and Treatment of Leprosy.—E. R. Rost, discovering that the bar to the cultivation of the bacillus lepræ is salt, has devised a plan by which he has obtained a medium free from this substance. By dialyzing nutrient agar in frequently changed warm distilled agar, a nutrient agar was obtained entirely free from sodium chloride, and on the surface of this medium the acid-fast group of bacteria grow very easily. The writer calls the toxin of the cultivation of the bacillus lepræ—leprolin. It is prepared on similar lines to the preparation of tuberculin. The writer, however, does not sterilize the cultures at all. He filters them through sterile Pasteur candles several times; he next reduces the fluid to one-tenth of the original bulk, and then refilters the fluid through resterilized Pasteur filters, the filters being previously tested. A leprolin prepared in this way will produce a powerful reaction in a case of leprosy which may last for three days or more. The dose is now 10 c. cm., injected into the muscles of the arms or buttock. The most striking effect of leprolin on lepers is the suddenness with which the sensation returns in the anesthetic patches. In almost every case injected with this material there has at least been some obvious return of sensation in some anesthetic area. The next noticeable effect is the alleviation of the shooting pains in the limbs and joints which follows the injection. The heavy sensation in limbs also disappears. The skin becomes normal in color and smooth, and the nodules in the subcutaneous tissues subside. The ulcers heal. Even gangrenous parts slough off, and leave healthy granulating tissue. The same effects are not always produced by the same preparation. Generally speaking, the severity of the reaction may be taken as an index of the benefit that will occur. The writer has practised over four hundred injections, and in no case has there been any bad symptom, and in every case the disease has ceased to advance. Of the total number of cases now treated by this method, four have been cured. At least no sign of the original disease remains. The writer believes that the theory that the disease is caused by the consumption of badly-cured fish, is erroneous.

Cutaneous Anthrax Successfully Treated by Sclavo's Serum Without Excision.—Anthony Bowlby and F. W. Andrews record a case of this kind. The patient was a horsehair dresser, thirty years of age. He presented himself with a characteristic anthrax lesion on the forehead. He had fallen some days before, striking his forehead against the fender. The skin, however, was not broken. Four days later watery fluid exuded from the bruise, and a black slough developed in the center of the bruise. The neck became a little stiff, and on the next day an enlarged gland was felt at the angle of the jaw. The general health was hardly affected, and there was little pain. The fluid from the vesicles showed numerous characteristic anthrax bacilli, and cultures yielded a profuse growth of the bacillus practically pure. The bacillus was virulent when tested on a mouse. The only treatment was the injection beneath the skin of the abdomen of 40 c. cm. of Sclavo's serum. The slough was kept covered by a piece of lint, coated with boracic ointment. The temperature fell to normal. There were no constitutional symptoms. The gland at the angle of the jaw diminished in size, but there was some edema. This was never extensive enough to close the eye, however, and it disappeared within a few days. The patient's convalescence was uninterrupted, and the slough separated fourteen days after the administration of the serum. Only nineteen hours after the administration of the serum, not a single colony of anthrax could be obtained from the fluid taken from the vesicles. This case seems to indicate that at least in moderately early cases of cutaneous anthrax, excision may be safely dispensed with, where an initial dose of 40 c. cm. of the serum is employed.

Recurrent Vomiting in Children.—H. Batty Shaw, R. H. Tribe, and Fredk. Langmead report cases of this affection. Recurrent vomiting of children begins generally after the first year of life, though it may occur at the second month, and may persist to the eleventh year. In some cases the symptoms pass off altogether; in others, they develop into migrainous attacks, while death has resulted in certain instances. Sometimes a prodromal stage is noticed. Constipation is common and may resist all treatment. Thirst is very common and very intense, due to the loss of fluid. The appetite is gone. The attack of vomiting may cease as suddenly as it began, and the child resume its former condition. In the earlier cases the breath is described as foul; more recently, the characteristic sweet, musty odor

has been ascribed to the presence of acetone. The condition of some of the worst of these cases is similar to that of a fatal case of diabetes. Acetone, diacetic acid, and oxy-B-butyric acid are present in the urine. Indican has been found in a few cases, and so have albumin and casts. The abdomen may be distended or retracted. The prognosis is as a rule, favorable. Convalescence is abrupt. As to the etiology, the influence of an hereditary neurotic tendency is generally admitted. Beyond this there is much uncertainty. When the first attacks occur, the diagnosis may be very difficult. As to treatment, the recognition of the acid-poisoning element has provided an argument for the administration of large doses of bicarbonate of soda. The general rule before the attack is to administer mild aperients, to give easily digested food, and to administer bromides and febrifuges. In attacks, it is wise to exclude all food except barley water and broths. Infusion of normal saline solution per rectum or subcutaneously, is useful. Sodium bicarbonate seems to be at least of some use.

A Case of Long-Standing Constipation.—Harry Grey describes this interesting case. The patient was 13½ years old, and for eleven years his bowels had as a rule moved only at intervals of from three to six weeks. On one occasion, two months elapsed between the acts. Castor oil had no effect. Occasional colic, and vomiting, faintness and headaches were the main symptoms. Lately he had complained of pain in the front of his thighs. His physical and mental development, however, had been much retarded. In the first week of treatment, the writer removed 26¼ pounds of nearly solid fecal matter, one day's record being 7¾ pounds in four movements. An infantile condition of the descending colon was present. At one time the mother had given the boy a glassful of whiskey, which was followed by a copious evacuation. This was probably due to its sedative and analgesic action upon the sphincter muscle. The writer found the sphincter firmly contracted, and administered ¼ grain of cocaine by suppository. After this he was able to pass a finger into the rectum. The boy was then put on morphine in the form of 1-6 grain suppository given three or four times daily, and the feces were then removed by enemata of hot olive oil, 30 ounces twice a day. These were continued for nine days until the color of the fecal matter had begun to change from slaty blue to more normal brown, by which time 29¾ pounds had been voided. A suitable dietary, with an emulsion, a pill of aloes and iron, four times a day, massage to the whole body especially the abdominal muscles, and gymnastic exercises were ordered. The pills were gradually reduced, till now for two months no medicine has been taken. The boy has had an evacuation every day to the minute. He has lost the peculiar facial appearance and protuberance of the abdomen. He eats well and sleeps well, and is making great progress in his studies, in which he was very backward.

Ergot and Arsenic in Chorea.—Clive Riviere has tried the effects of the administration of ergot and arsenic in combination in the case of choreic patients with excellent results. He believes that its good effects embrace three kinds of cases: Those that are benefited by ergot; those that are susceptible to arsenic; and those, perhaps few in number, in which the one drug seems to supplement the other. In the majority of cases, improvement begins at once. The unbenefited cases consist mainly of those violent choreas for which so little besides isolation can be done. The writer begins with a mixture containing 1 drachm of extract of ergot and 3 minims of liquor arsenicalis, these doses being increased as seems desirable.

Berliner klinische Wochenschrift, February 6, 1905.

The Nature of Typhoid Immunity.—Jürgens describes the case of a man of fifty who recovered from a severe attack of typhoid fever, during which the Widal reaction was positive and the bacilli were recovered from both blood and stools. The patient returned home, and for two months was in good health so that he was able to go back to work. At the expiration of this time he was again taken sick with typical typhoid symptoms and went through the usual course of the disease. In considering this case, which may be regarded either as a very late relapse or as a reinfection, the author arrives at the conclusion that the process of immunization does not depend on the infective microorganism alone, but is in addition modified by various individual factors. The results of experimental typhoid infections in animals cannot be directly applied to the study of the disease in man, and the determinations of the agglutinating and the bactericidal properties of the serum in the present instance indicate that immunity may not be caused, even if the formation of agglutinating and bactericidal bodies is normal. The fact that in localities where typhoid is endemic the disease in the course of time assumes a milder character, goes far to confirm the view that some still unknown elements are concerned in the production of immunity.

The Significance of the Recent Attempts to Infect Animals with Syphilis.—Hoffmann reviews the results obtained by various syphilaographers in their attempts to transmit syphilis to the higher monkeys and other animals. Experiments with the lower animals have all failed, and though Piorkowski, on the strength of a single observation, claims to have produced syphilitic lesions in a horse by the injection of human infected blood, and even begins to speak of serum therapy, but little importance can be attached to this isolated observation. Roux and Metschnikoff have reported several successful inoculations on chimpanzees, and have been able to transfer the disease from one animal to another. These authors have attempted to approach the subject of protective inoculation by attempts to reduce the virulence of the contagium by passage through a less susceptible type of monkey. Material obtained from the comparatively slight lesions of the macac appeared to confer a high degree of resisting power to the chimpanzee, but here again the experiments are still too few to permit of generalization. Although decided progress has been made, and it is to be hoped that Neisser's projected visit to the Sunday Islands for the purpose of carrying out extensive series of experiments in a region where the monkeys are readily obtainable, will prove of great value, at present mercury and iodine are still the only remedies for the disease at our command, and it is dangerous to resort to untried measures in the treatment of a malady so prone to late recurrences as is syphilis.

Münchener medizinische Wochenschrift, February 7, 1905.

The Effect of High Altitudes on the Blood.—Bürker undertook to ascertain the nature of the blood changes occurring in high altitudes, which have been made the subject of contradictory reports by different observers. The first question was to ascertain whether Gottstein's allegation that the counting chamber underwent appreciable changes sufficient to account for the high red cell counts obtained in elevated regions, were so or not. It was found that the chamber itself was slightly altered in its physical characters, but that this change was too slight to introduce any great error into the results obtained. On the other hand, differences of temperature have a marked effect in disturbing the even distribution of the cells on the bottom of the chamber, and this feature may perhaps explain some of the discrepancies reported. Tests of the coagulation time showed a slight increase in rapidity in high altitudes. Analysis of the liver and blood of animals at sea level and in the mountains showed that there was first a rise followed by a marked diminution of the iron content of the liver soon after reaching the high altitude, while the blood became richer in the same substance. The author's observations indicate that the change from low to high altitudes produces specific alterations in the composition of the blood, which are actual and not relative, though their cause is still undetermined.

The Diagnostic Significance of Eosinophilia in Ankylostomiasis.—Bruns, Liefmann and Mäckel consider this question from the standpoint of the sanitary control of the inhabitants in mining districts. English authors are inclined to consider the systematic examination of the feces for eggs impracticable, and prefer to draw conclusions from differential leucocyte counts. The German investigators do not altogether agree with this view, for while their investigations of 500 cases showed that in general the presence of ova in the feces was attended by an eosinophilia of over 8 per cent., while 92 per cent. of the patients had over 5 per cent. of eosinophiles, they do not believe that the blood examination alone would justify subjection of the individual to anthelmintic treatment, so that the feces would require examination in any case. They also maintain that a large number of fecal examinations can be made with less expenditure of time and trouble than a corresponding number of differential counts, and they have never encountered the objections on the part of the miners to submitting authenticated stools that the English authorities mention. While blood examinations of a large number of miners will give a fair idea of the prevalence of infection in a certain district, fecal examination of those not exhibiting eosinophilia should not be omitted, as otherwise infected persons might easily be overlooked. In individual cases, however, the presence of eosinophilia, even with negative stools, is always of value as indicating the probable existence of intestinal parasites.

The Dangers of Schultze's Method of Artificial Respiration.—Burckhard says that although Schultze's method of reviving asphyxiated infants is undoubtedly most effective, it is not altogether without danger. The energetic swinging of the body involved can easily lead to the various hemorrhagic lesions described by several authors, and he himself in autopsies on infants that had been subjected to this means of artificial respiration has discovered cerebral and spinal hemorrhages. The occurrence of spastic palsies or Little's disease in infants asphyxiated at birth is referred

to the presence of meningeal hemorrhages, and these may easily follow the Schultze maneuver. Still the number of such cases is not large, and Hengge's recommendation to use Schultze's method only rarely and to rely on other measures, is hardly justified. Great care is needed, however, especially with premature infants, and the technique of the procedure must be thoroughly mastered in order to avoid injury to the child.

French and Italian Journals.

Epididymitis Due to the Bacillus of Eberth.—Manson reports the case of a man aged 35 years who was convalescent after an attack of typhoid fever. He was amusing himself in his garden one day, uprooting a little tree, when he felt a pain in the right testicle, which he attributed to a strain. On the next day his temperature rose, and a very painful swelling of the head of the epididymis developed. For seven or eight days the swelling increased, with slight reddening of the edematous mass. An indurated tumor was clearly palpable. It was painful on pressure, of the size of a large nut, and located at the head of the epididymis. The diagnosis of suppurating epididimytis with a possibility of tuberculosis, was made. The ureter, prostate, and vas deferens were not involved An incision was made, followed an outflow of thick pus, resembling that of a cold abscess. The cavity was curetted and tamponned. The patient recovered in eight days. Examination of the pus revealed the presence of Eberth's bacillus. The affection was a complication of typhoid fever, having developed, as is common, from the twenty-fifth to the thirtieth day.—*Le Bulletin Médical,* January 28, 1905.

Cyst of the Cerebellum.—Ménétrier and Gauckler observed the following case. The patient was a man 28 years old, who was brought to the hospital after an atttempt at suicide. For a long time he had suffered from violent headaches. This pain had driven him to attempt to take his own life. For some time also, the patient had been addicted to the use of alcohol. He had to retire from the army on account of his illness. For five years pain in the head persisted. He was also troubled with vomiting, which occurred without effort, and his gait became affected. The vomitus was clear, bilious, and abundant. It had all of the characteristics of cerebral vomiting. The patient constantly lost his equilibrium. He fell sometimes to the right, sometimes to the left. Walking and standing became impossible with the eyes closed. A lesion of the cerebellum was diagnosed. He denied all venereal disease. Antisyphilitic treatment had no effect. The bromides, chloral, and aconitin, each tried in turn, met with negative results. Lumbar puncture was practised, with the result that a jet of liquid spurted out as if it had been held under high tension. There was no deposit after it had been centrifugalized. The patient gradually sank into a stupor from which he aroused only to complain of his pain. Death came suddenly. Autopsy revealed a cyst of the cerebellum. It was as large as a mandarin, and occupied the entire median part of this organ, replacing its tissue, save in a small area behind. The aqueduct of Sylvius was greatly dilated. The cyst contained a clear, abundant liquid under increased tension. It was not albuminous. The cyst was not neoplastic.—*Revue Française de Médecine et de Chirurgie,* January 16, 1905.

Epithelial Embryonic Tumor of the Inguinal Region.—Reverdin operated upon a man of thirty-one years for an inguinal tumor. The patient was not very intelligent, was myopic, and showed an arrested development of the genital organs. A slender cord was terminated by a small prepuce. In the scrotum there was no trace of testicles. The external orifice of the left inguinal canal was effaced. On the right, the canal was filled up by a tumor mass, flabby on the anterior surface, but hard at the abdominal end. The urinary functions were normal, the genital sense nil. At operation a mass was found filling up the inguinal canal, and composed of a lower flabby part, and of an upper part composed of omentum and an intestinal coil. These tissues were freed, the intestine reduced, and the omentum and tumor mass resected. The wound healed by first intention. Careful study of the cellular elements suggested that the growth was an epithelial embryonic tumor. —*Le Bulletin Médical,* January 28, 1905.

Treatment of Varicose Veins by Walking.—Marchais believes that massage and activity influence varicose veins by modifying the circulation, by reviewing the compression of the deep veins, and by causing the periphlebitis to subside. Patients who suffer with varicose veins have poor muscles. Walking rejuvenates the muscles and physiological compression advantageously replaces elastic stockings. Massage acts on the periphlebitis and walking is really physiological massage.—*La Tribune Médicale,* February 4, 1905.

Enterocolitis in the Tropics.—A. Thiroux declares that this affection is very common in the tropics, and is characterized by constipation and buccal aphthæ. Manson has designated it as sprue with constipation. The writer has often observed this disease in Europeans who were living in the Antilles, and in Africa. Its frequency has been noted in China, also. It is often thought to be malaria. The first symptom which manifests itself is generally a congestion of the intestinal canal including the neighboring glands—the liver especially, with very often continuous fever. The alternations of diarrhea and constipation or absolute constipation, the voiding of diphtheroid membranes, the buccal aphthæ, and the nervous and psychical symptoms generally suffice for making a diagnosis. Emaciation is not constant. The complexion becomes more or less ashy. The patients generally complain of a feeling of lassitude, and of marked loss of memory. They become irritable and aggressive. Nervous asthenia often develops. The prognosis is not immediately grave, for the illness is of long duration. But if the patient is not subjected to a severe regime, his condition becomes worse and worse and he is likely to succumb to some intercurrent affection, which he is not strong enough to resist. As to treatment, daily intestinal douches are most valuable. Diet is very important. The writer does not advocate the use of milk in this affection, but believes that a mixed diet, with some restrictions, will give the best results. Fats ought to be banished. Shell-fish and fish are forbidden. Fruits and vegetables, except cabbage, may be allowed. Alcoholic drinks and smoking are prohibited. Change of climate is necessary sooner or later. A sojourn at a resort where alkaline waters are to be found is advantageous. But under all conditions the illness is always a long one.—*Gazette des Hôpitaux Civils et Militaires,* February 4, 1905.

Maxillary Sinusitis with Exophthalmos and Optic Neuritis; Recovery.—Marcille and Galezowski state that purulent maxillary sinusitis or maxillary empyema is often accompanied by oculoorbital phenomena. This is explained by the delicacy of the orbital plate. These complications are not infrequently very severe. The patient whose case is here reported was a young man of 25 years. He presented himself in October with considerable exophthalmos of the left eye. The exophthalmos was not pulsatile, and the right eye was normal. There was no movement of the left eyeball. The eye seemed actually congealed. Eight days before, the patient had experienced sharp pains in the left eye and in the head. The eye soon became red and inflamed. The first large upper molar was found to be carious and was extracted, but in spite of this the condition became worse. There was a discharge of pus from the left nostril. The three symptoms: unilateral exophthalmos, a carious tooth, and a purulent discharge from the nostril, were the grounds for the diagnosis of maxillary sinusitis. However, there was no painful point. A careful ophthalmoscopic examination was made, and the presence of optic neuritis was noted. Another examination of the mouth discovered one root of the affected tooth still left. This was extracted, but the exophthalmos only increased. Operation was decided upon. On entering the orbit no pus was found, but the bony tissue was completely altered. A sound was passed into the sinus with no resistance. The sinus was opened on its anterior surface, and bloody, fetid pus escaped. Fungoid growths in great quantities were removed, and after the cavity was cleaned out as thoroughly as possible, the internal wall was perforated to establish a communication between the sinus and the nasal fossæ. A drain was then passed from the nostril into the sinus. Another drain was placed at the lower external part of the orbit, and the wound was closed. Improvement began. The result of the operation was excellent. Suppuration was quickly arrested, and the optic nerve became entirely normal again.—*La Tribune Médicale,* February 11, 1905.

Dangers of Interstitial Injections of Camphorated Naphthol.—M. A. Broca, after making a study of the various topical injections which are the most often employed in cases of cold abscess and tuberculous ganglia, quickly came back to the use of iodoform ether. He was influenced only by the fact of its efficacy, and not because he considered it less harmful. He declares that he is more than skeptical as to the efficacy of camphorated naphthol. From 1890 to 1892 he used it for ulcerations, and for injections in cold abscesses, and in unsoftened ganglia. He abandoned its use because it seemed to him less active than iodoform ether. Recently a number of deaths have been reported from the use of camphorated naphthol. Besides this clinical evidence, it has been discovered experimentally that camphorated naphthol is very toxic for the rabbit and guinea pig, far more so than is either camphor or naphthol by itself. It has been noted in man that without any fault of technique, 5 c.c. injected into a ganglion may cause death.—*Revue Française de Médecine et de Chirurgie,* February 13, 1905.

Action of the X-rays on the Blood.—Aubertin and Beau-

jard have studied the effect of the *x*-rays on the hematopoietic organs, for here the effects are more marked than on the other tissues. An animal subjected to the entire action of the rays immediately shows the presence of leucocytosis, and a manifest leucocytic histolysis becomes evident. Irradiation on one spot produces a temporary leucocytosis. Repeated sittings, the treatment being directed to one segment, cause a progressive increase in leucocytes. The red corpuscles diminish in number and become altered, and nucleated reds become abundant. The white corpuscles then diminish. There is then a leukemia with myelemia. In the healthy animal as in the leukemic patient, there is leucocytic emigration and destruction in the beginning, and at the end degeneration of the tissue that has been subjected to the *x*-rays.—*Le Progrès Médical,* February 11, 1905.

Immediate Trephining in Compound Fractures of the Skull.—Aldo Cernezzi advocated immediate operation in all compound fractures of the cranial bones of the vault, even if there are not signs of compression. He believes that the dangers of sepsis from opening the skull cavity are counterbalanced by the advantages of removing all detached fragments of bone, cleaning out clots, and rendering the field of the wound perfectly aseptic. This he considers as good surgery in the skull as in the compound fractures of the long bones. He cites a case in which there were no signs of compression except localized paresis in the upper and lower extremities of one side, which was operated on as soon after the accident as seen, in which there was complete recovery of motion in five weeks from the accident.—*La Riforma Medica,* January 21, 1905.

Effect of Work in Tobacco Factories on Reproductive Functions in Women.—Guido Pieraccini has examined the clinical records of the obstetric clinic in Florence, with a view to ascertaining whether the female workers on tobacco have more frequent interruptions of pregnancy than other women. The records examined include the years from 1894-1903; there were eighty-four cases from tobacco workers, who came to the hospital for treatment for pregnancy; of these forty-nine were delivered at term, sixteen prematurely, fifteen aborted, and four cases were threatened with abortion, of which three were afterward terminated prematurely; thus we have 36.90 per cent. of interrupted pregnancies. During the same period, of patients not tobacco workers, 386 in number, only 21.50 per cent. had premature deliveries. Hence, the author concludes that tobacco work had a bad influence on the continuance of pregnancy. This is brought about either by an intoxication conveyed through the placenta, killing the fetus, or by nicotine directly stimulating the uterus to contraction. Nicotine, however, does not seem to prevent conception.—*Gazetta Medica Lombarda,* January 23, 1905.

Cancer-Cirrhosis of the Liver.—Elmaro Rollino discusses the coexistence of cirrhosis and cancer in the same liver, and the questions which of the lesions was the primary one, and whether the same exciting cause was at the basis of both lesions. He brings forward one case of his own, and two others collected from literature, in which the two lesions undoubtedly existed together, as shown by autopsy, and analyzes the previous history, concluding that the cause of the condition was a long-continued gastroduodenal catarrh, with retardation of the flow of bile in the capillaries of the liver; this resulted in cirrhosis, which acted as the predisposing cause of cancerous formation in the liver.—*La Riforma Medica,* January 28, 1905.

Good Effects of Radiotherapy in a Case of Lymphatic Leukemia.—M. E. Gerber has been treating a man of 58 years by this method. The patient came for relief, suffering from leukemia, with multiple adenopathy, splenomegaly, and very accentuated lymphemia (20,800 leucocytes, of which 16,000 were lymphocytes, 4,350,000 erythrocytes, the hemoglobin ranging from 80 to 90 per cent. The patient was treated by the *x*-rays for some days, the rays being focused on the ganglionic masses, on the spleen, and on the flat bones of the thorax. The results of the treatment were very encouraging, although Gerber does not consider the cure as assured. The ganglia and the spleen decreased in size, and there was a diminution in the number of leucocytes. Holzknecht has already treated twelve cases of leukemia by means of radiotherapy. In all of these cases he has noted a decrease in the number of leucocytes, a diminution in the size of the spleen and the ganglia, and a considerable increase in the number of erythrocytes. Although there seemed to be an improvement in the different ailments of the patients, the general condition remained grave. Both of these workers hold that radiotherapy does not result in recovery in cases of leukemia, but brings about improvement more or less durable. This result alone, however, would justify the employment of this method.—*La Presse Médicale,* January 21, 1905.

Chronic Iliocecal Invagination.—Annibale Passaggi records a rather rare case of ileocecal invagination that had occurred so many times during a period of two months that it might be called chronic. Every few days the patient would suffer from a more or less prolonged crisis of intestinal obstruction, accompanied by violent colicky pain, vomiting, and the appearance of a tumor in the epigastric region, which after a time disappeared, with a disappearance of the symptoms of obstruction. This occurrence was twice observed in the hospital before the operation. The tumor was placed like the transverse colon and transmitted the aortic pulsations. Palpation gave a sensation of resistance, and a fixed tumor could be felt. At the time of operation the tissues were found not much swollen or changed, and of good vitality, while the portion above the invagination was much dilated. There were enlarged glands in the mesentery, indicating a permanent inflammatory condition of the mucosa of the intestine. The author considers it rather unusual that no adhesions had formed between the diseased portions of the intestines.—*Il Policlinico,* January, 1905.

Transposition of the Heart Toward the Right in Increased Left Endopleural Pressure.—Attilio Gervine, from observations of two patients and experiments on the cadaver, concludes that in transposition of the heart in such conditions as pyopneumothorax, the change of position involves the whole heart; the heart does not move as a pendulum, as some authors have stated, this movement being anatomically impossible, and in the cadaver being found not to take place. He finds that the portion of the heart that gives the impulse on the chest wall is not the apex, but the right auricle, much dilated, which, during systole, is pressed against the chest walls. The author injected the chest after death and found this position of the heart to be caused by increased intrathoracic pressure.—*Il Policlinico,* January, 1905.

The Diagnosis of Rabies.—Lina Luzzani publishes the findings in 177 cases of suspected rabies sent for examination to the Antirabic Institute of the University of Pavia. Examination was made as to the presence of the parasite of Negri, especially as found in the cornu ammonis and cerebellum, which are the most frequent location of the microorganisms. Positive diagnosis of rabies was made in every case in which the bodies of Negri were found; control inoculations were made in rabbits. The suspected animals consisted of 163 dogs, 12 cats, an ox, and a horse. Of the 177 animals, 106 were found to have rabies, and in 101 cases the diagnosis could be made from the examination of the cornu ammonis alone. The author sums up 455 cases examined by various authors, in which 296 were found to have rabies; Negri's method has enabled a positive diagnosis to be made in 287 cases; the author regards the presence of the parasite of Negri as a certain criterion for diagnosis in rabies.—*Archivio per le Scienze Mediche,* Vol. XXVIII, No. 4, 1904.

Deaths Among Medical Men.—Recently published statistics show that in Austria heart disease is accountable for by far the largest proportion of deaths among medical practitioners, amounting to 44 per cent. of the whole number. Disease of the nervous system is responsible for 20 per cent., and an almost equal proportion is attributed to morphinomania. Tuberculosis claims only 7 per cent., a fact that seems to show that medical practitioners practise their own precepts as to the prevention of diseases in this particular field of pathology more strictly than in some others. —*Medical Age.*

The Largest University.—The year book of the German universities, just published, makes it clear that Berlin University is the most numerously attended seat of learning in the world. It contains 7,774 matriculated and 1,330 non-matriculated students. The philosophical faculty, embracing philology and natural sciences, numbers 3,572 students —medicine, 1,111; law, 2,756, and theology, despite the eminence of its professors, only 335. America sends 123 students, Africa 8, Australia 3, and Asia 37.—*London Standard.*

Tattooing as a Means of Infection.—According to the annual report of the director-general of the medical department of the British navy, the practice of tattooing may be the means of transmission of disease. A naval surgeon reports the case of stoker who came under observation, complaining of a generalized skin eruption. On inquiry, it was ascertained that the man had been tattooed at Wei-hai-wei, and that in the midst of the region operated on a sore appeared. Considering the opportunities for infection afforded by the practice, it is surprising that such cases are not reported oftener.

Six Children in One Year.—The Munich *Neueste Nachrichten* announces that Frau Hilgen of Trostberg, in Bavaria, has borne no less than six children in one year. She was delivered of triplets last January, and bore triplets again this December.

Surgical Suggestions.

Foreign Bodies in the Eye.—Sydney Stephenson concludes an article on this subject with the following advice: After removing a foreign body from the cornea, never omit to render the parts as aseptic as may be and to keep the eye tied up until such time as the corneal epithelium is regenerated. Moreover, bear in mind that a polypus of the conjunctiva almost invariably denotes a foreign body, and that out-of-the-way corneal changes are not infrequently due to the same cause.—*British Journal of Children's Diseases.*

Infected Wounds.—Wiedow believes that incised wounds, especially where there has been considerable hemorrhage, are not very dangerous under ordinary conditions, and it is a mistake to apply strong antiseptics to all of these, as the wound never does so well afterward. In applying a strong antiseptic a thin layer of tissue in each lip is weakened or destroyed and affords soil for the growth of germs. If it is necessary to wash a wound of the above description out at all, sterile water or a sterile boric acid solution is preferable. If, however, there is reason to believe a wound to be infected, it should thoroughly be cleansed with a strong antiseptic. In many of these 95 per cent. carbolic acid followed with alcohol may be used with satisfactory results. Deep punctured wounds should be incised freely and treated as above. When the infection has already reached the lymphatics, careful search must be made for foci of pus, which should be incised and drained. Dr. Ochsner's solution containing one part each of 95 per cent. alcohol and 5 per cent. carbolic acid, and six parts of saturated boric acid solution is very valuable. It is poured into the dressing at intervals of from one to six hours—*Iowa Medical Journal.*

Prostatectomy.—Belfield says that the prostate should be removed only when the obstacle to urination is real hypertrophy of the prostate; when the urinary function cannot be restored by the retained catheter, etc.; and when the patient's condition warrants a serious operation.—*Colorado Medical Journal.*

Chancroids.—Carle recommends cauterization either with the actual cautery or with chemicals (1) for chancroids which come under observation in the first forty-eight hours, no matter what their situation or number; (2) for older lesions so placed as to make excision difficult or likely to be followed by undesirable cicatrization; (3) for multiple chancroids. For chancroids of the skin, frenulum, prepuce, etc., the following method of excision is advisable: The entire region is carefully cleansed, the chancroid frozen with ethyl chloride and excised either with curved scissors or with a razor. The wound is then closed by suture or is touched with nitrate of silver, dusted with iodoform, and covered with zinc plaster.—*Deutsche Medizinal-Zeitung.*

Cocaine Anesthesia.—Means says that Reclus, who reports 7,000 operations under cocaine anesthesia without a death, insists on the observance of the following rules: (1) Never use a stronger solution than 5 per cent. externally or 1 per cent. hypodermically. (2) Always have the patient recline during the administration of the anesthetic and not get up for half an hour after. (3) Always have the patient eat and drink something before rising.—*Columbus Medical Journal.*

Conversation at Operations.—Mendes de Leon says that in experiments carried on at operations it was found that the minute droplets of saliva expelled during conversation contain on an average 4,375 bacteria each. These are mainly streptococci, as well as diplo- and staphylococci, and in many instances are virulent. In order to remove this source of infection he has devised a little apparatus which does not interfere with articulation and catches the droplets of sputum in a layer of absorbent cotton.—*Archiv für klinische Chirurgie.*

Treatment of Scrofula by Injections of Sea Water.—G. Pagano has treated nineteen cases of enlarged glands in the neck. In various degrees of severity, by subcutaneous injections of sterilized sea water, with excellent results. He bases his treatment on his belief that the real value of sea baths is due to the absorption of the chemical contents of the water through the skin, and that the sea water contains several substances that are necessary to the chemical functions of the body. He injects at first 5 cubic centimeters into the subcutaneous tissue of the flank, afterwards increasing the amount to 20 cubic centimeters. He finds at first a slight febrile reaction, which soon passes off, and is followed by an excellent appetite, a general improvement, and a reduction in the size of the glands, or a healing of fistulous openings.—*Rivista Critica di Clinica Medica.*

Feeding with the Essential Fat of the Tubercle Bacillus.—D. MacDonald claims to have discovered that hydrous cholesterin-fat (wool-fat) gives the essential tests of the tubercle bacillus. When patients are fed with it, there is a marked increase in weight, and a favorable influence on the progress of various chronic wasting diseases. Attention is called to the facts that sheep and goats enjoy a comparative immunity to tuberculosis; this disease makes great havoc where sheep are not indigenous, as in Japan; and where sheep are prevalent, on a corresponding latitude, as in Iceland, there is a striking immunity to the disease. The writer briefly mentions many experiments in which the chromophilic potentialities of the tubercle and allied bacilli can be watched under the microscope in the tests for cholesterins, which are present in tuberculous and allied lesions. About half of the tubercle bacillus consists of fat, which explains the historical therapeutic value of the latter. Animals with a high percentage of butter fat in their milk enjoy a comparative immunity to tuberculosis. This disease selects the fatty tissues, and where there is no fatty basis, as in the lungs, it is rare. A fatty degeneration of the epithelium is requisite to fallow the soil. In a great measure, infancy is free from scrofula and tuberculous meningitis, and excepting the tuberculous sequalæ of some of the infectious diseases, it is a comparative antituberculous period of life. In infancy there is an enormous increase in flesh. To destroy the tubercle bacillus with its own weapon, it is necessary to produce a fatty degeneration in it. Cholesterin-fat contributes admirably. The solid fats of the bacillus becoming liquid, emulsify and become rancid. This increases the soluble fatty acids, diminishes the glycerol produced on saponification, increases slightly the volatile acids, decreases the insoluble acids, and greatly increases the free acids. When the bacilli lose their acid-fast properties, the way is being paved for their solution and absorption. The essential fat of the tuberculous plant can be administered in various ways—by enema, by hypodermic injection, by friction into the armpits, back, abdomen, and by ingestion. It can be given in food before or after it is cooked, or taken alone. It can be taken in health or disease. The weight increases several pounds a week. It is solid at ordinary temperatures, thus it may be administered in various vehicles which will accelerate its administration and action. The dose may be from half a drachm upward in various other oleaginous vehicles.—*Medicine.*

Treatment of Alopecia Areata with Currents of High Frequency.—Luigi Vardiani records the treatment of a case of alopecia areata of a year's standing, which had been rebellious to all forms of treatment. The disease involved three-fifths of the entire scalp, as well as a large portion of the beard. The patient was 48 years of age, in the best of health and in good circumstances. He had had rheumatism and multiple osseous lesions, probably tubercular, as a child, and was of a nervous habit. The disease reached its full severity in fifteen days from its beginning, leaving many circular bare spots in scalp and beard, over which the skin looked normal, with no vesication or desquamation. High frequency current was used at first only on the scalp; duration of the application two to eight minutes, for 24 sittings. Hyperemia of the skin was produced to varying degrees over different locations, where it was greatest being the spots that were most quickly covered by hair. The hairs were at first fine and white, then became thicker and for the most part black, a few being white, corresponding with the hair over the normal scalp. The cure began from the periphery of the patches, extending in toward the center. The beard was not at all improved until direct applications were made to its bare areas. The recovery of the case was complete. The author believes that this case tends to show that this is a disease caused by a discrasia rather than by a parasite, as shown by the centripetal effect of the current.—*Rivista Internazionale di Terapia Fisica,* December 1, 1904.

Book Reviews.

Diet in Health and Disease. By Julius Fridenwald, M.D., Clinical Professor of Diseases of the Stomach in the College of Physicians and Surgeons, Baltimore, and John Ruhräh, M.D., Clinical Professor of Diseases of Children in the College of Physicians and Surgeons, Baltimore. "These few rules of diet he that keeps, shall surely find great ease and speedy remedy by it"—Burton. Philadelphia, New York, London: W. B. Saunders & Company, 1905.

This very comprehensive book of 689 pages has been written especially for the use of the general practitioner, medical student, hospital interne, and trained nurse. The whole tone of the work is practical. The various kinds of foodstuffs, their uses and chemical composition are discussed. The chemistry and physiology of digestion, including such subjects as American and European dietaries and dietary standards, the influence of various factors upon the digestion, and the relation of food to various inherent conditions, are considered. Although the principles of diet both in health and disease are given, special attention is paid to the subject of diet in disease. In all the diseases in which food plays a part, dietetic management is carefully considered. The doctor is told how to feed his patient, numerous diet lists and explicit directions for administration being given. Beverages and stimulants are treated in an interesting manner. The literature—much of which is inaccessible to the general practitioner—has been thoroughly searched and the most useful parts of it have been incorporated here. Various factors in their bearing on diet, such as concentration of food, preservation of food, artificial foods, food poisoning, food adulteration, and diet as a means of diagnosis, make an interesting section. The diet of infants and children, of patients before and after anesthesia and surgical operations, and the latest methods for feeding after gastrointestinal operations, are treated with the most careful detail. In the section on rectal enemata, recipes and full instructions as to technique are given. Special cures are discussed, also army and navy rations and dietaries in public institutions. Many diet lists and recipes are given which are of great value. The authors are to be congratulated on the presentation of a book which is worthy of their reputation.

Practical Dietetics. By A. L. Benedict, A.M., M.D., Councilor American Gastroenterological Association; Fellow American Academy of Medicine; Consultant in Digestive Diseases City Hospital for Women, and Riverside Hospital, Buffalo. Chicago: G. P. Engelhard & Company, 1904.

The writer in his preface states that dietetics must rest, even more firmly than medicinal therapeutics, upon the principles of physiology. His aim in this volume has been to present mainly the principles and facts upon which the proper nourishment of the body depends, whether in health or disease. He considers first the chemical basis of dietetics, following this with chapters on proximate principles (proteids, albuminoid foods, carbohydrate foods, fats and oils and so on), and inorganic proximate principles (salts, iron, phosphorous compounds). Dietetic needs in health and food requirements in terms of natural foodstuffs next claim attention. Perhaps the most interesting and practical part of the book is that treating of specific foods and dietetics of the period of growth. The latter half of the text is given up to the consideration of food in various diseased conditions—diabetes, obesity and leanness, fevers, stomach, hepatic, renal, intestinal, respiratory, cardiac and nervous diseases and so on. This valuable book is supplied with an excellent index.

Handbook on Sanitation. A Manual of Theoretical and Practical Sanitation for Students and Physicians; for Health, Sanitary, Tenement-House, Plumbing, Factory, Food and other Inspectors, as well as for Candidates for all Municipal Sanitary Positions. By George M. Price, M.D., Medical Sanitary Inspector, Department of Health, New York City; Inspector New York Sanitary Aid Society of the Tenth Ward, 1885; Manager Model Tenement-houses of the New York Tenement-house Building Company, 1888. Inspector New York State Tenement-house Commission, 1895. Second Edition, Revised and Partly Rewritten. New York: John Wiley & Sons; London: Chapman & Hall, Limited, 1905.

In the present edition the editor's aim has been to increase the usefulness of this book for sanitary inspectors in Health Departments as well as for others interested in this subject. With this object in view, he has brought the text completely up to date, omitting all material of merely local application. The text of the first part of the book has undergone considerable revision, while the fourth part dealing with sanitary law, has been entirely eliminated. The section on Sanitary Inspection has been expanded. The section on Sanitary Practice, including "Habitation," "Occupation and Trades," "Food," and "Disinfection," has been entirely rewritten, and will prove of great value to all workers in these lines.

The Summer Diarrheas of Infants. Their Etiology, Pathology and Treatment. By H. Illoway, M.D., Formerly Professor of Diseases of Children, Cincinnati College of Medicine and Surgery, formerly Visiting Physician Jewish Hospital, Cincinnati; one of the collaborators on the American Text Book of Diseases of Children; Fellow of the New York Academy of Medicine, etc. New York: E. R. Pelton, 1904.

In this little book the author considers heat stroke in infants (thermic fever), summer complaint, and cholera infantum, giving at the end a summary of the results of his studies and observations. The histories of several cases are cited. A short bibliography is appended, but there is no index.

Medical Electricity; a Practical Handbook for Students and Practitioners, by H. Lewis Jones, M.A., M.D. Fellow of the Royal College of Physicians; Medical Officer in charge of the Electrical Department in St. Bartholomew's Hospital, London; President of the British Electrotherapeutic Society; Honorary Fellow of the American Electrotherapeutic Association; Member of the Société Française d'Electrothérapie et de Radiologie. Fourth edition, with illustrations. Philadelphia: P. Blakiston's Sons & Co., 1904.

This well-known book is now in a fourth edition, and, having thus amply justified its existence, it is only necessary for us to note wherein the present issue differs from former editions. The subject matter throughout has been revised, and chapters have been added on high frequency electricity and on the utilization of current from street mains for medical and surgical purposes; the chapter on the Röntgen rays has been enlarged. There is an appendix containing a list of places having a public electric light supply, with some details of the character of the current furnished. This is very useful for those living in England; but for American readers this list might well have been omitted, and a similar one of American towns inserted. The book is written by a well-known expert, and it is a particularly reliable and lucid presentment of an important subject.

Æquanimitas, with Other Addresses to Medical Students, Nurses, and Practitioners of Medicine. By William Osler, M.D., F.R.S., Professor of Medicine, Johns Hopkins University. Philadelphia: P. Blakiston's Son & Co., 1904.

This is a collection of eighteen addresses delivered on various occasions between 1889 and 1903. The diversity of subjects is wide—"Doctor and Nurse," "Physic and Physician as Depicted in Plato," "The Army Surgeon," "Teaching and Thinking," "Chauvinism in Medicine," "The Hospital as a College" being some of the titles—but they are all handled in the charming style which has made the author facile princeps among medical writers in the English tongue. If we had to pick out the best of all these addresses our choice would be the last, entitled "The Master-Word in Medicine"—a panegyric of work, the perusal of which would shame the laziest of men to action.

An Introduction to Pharmacognosy. By Smith Ely Jelliffe, M.D., Ph.D., Professor of Pharmacognosy and Instructor in Materia Medica and Therapeutics in Columbia University (College of Physicians and Surgeons), New York. Fully Illustrated. Philadelphia, New York, and London: W. B. Saunders & Company, 1904.

The study of pharmacognosy has had its due share in the increase of scope which has been given to nearly all branches of instruction in the undergraduate courses of our medical schools, and the present volume is of a nature to form a most desirable addition to the works on the subject available for the student's use. Of the ordinary type of textbooks on materia medica, there are many good examples, but there is no other work of small size in which the histological characteristics of the various drugs are so fully described and so clearly pictured. The pharmacognosy of each drug, including the gross appearance, chemistry and adulterations, is given in readable but concentrated form, and in instances in which the detection of adulteration in powders is possible by the use of the microscope the structural elements which should be found in pure specimens are depicted in clear-cut line drawings. The sophistication of powdered drugs is notoriously prevalent, and the intelligent use of the microscope affords one of the readiest modes of detecting frauds, so that the value of a satisfactory guide to such examinations is most apparent. Though ostensibly prepared for the use of students and of pharmacists, the authoritative and unique character of this book renders it of the greatest importance and value to the practitioner as well. The press work, paper, and binding are very pleasing, and reference has already been made to the unusual interest of the figures.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 9, 1905.

DR. L. E. LA FÉTRA IN THE CHAIR.

A Case of Enlarged Spleen, with Report of Blood Changes.—Dr. ELI LONG, JR., presented a negress, aged 11 years, who had come under observation one year ago, and the appearance of the blood, especially at that time and since, justified him in presenting the child to the Section. The family history was negative. She had one older sister and two younger brothers, and all were healthy, except for the manifestation of rickets. The patient was a perfectly healthy baby up to the age of one year, when she began to have attacks of bronchitis, and from then on she was more or less delicate. At the age of three she had pneumonia, and during convalescence began to have attacks of epistaxis, which had appeared off and on ever since. One year ago she had an attack of measles without any complications. Five years ago she had an indefinite chill, or rather, a chilly sensation, which came on every other day for one week. Her last chill occurred four weeks ago, and previous to that, last spring. This was a very indefinite malarial history. The present illness practically began one year ago, when the child complained of pain in the "stomach." This was especially severe after eating. The child one year ago presented practically the same condition as at present. The treatment employed had been of no consequence. One year ago the child was practically healthy, except for her color, which seemed to be lighter than normal, so far as could be noted in a colored child. An examination revealed nothing wrong, except an enlarged spleen. The anterior border reached to the umbilicus and was sharply notched. The inferior border was two fingers breadth below the umbilicus. The organ was hard and almost nodular. The liver was also moderately enlarged. The doctor said the most interesting part of the case was in the diagnosis; he made one last year, but he was compelled to change it.

Dr. L. B. GOLDHORN said that from a clinical point of view the case presented no departure from the ordinary; but from a hematologist's point of view it did decidedly. During the past year they had made a number of blood examinations. Last year there were 2,500,000 red cells; hemoglobin, 42 per cent., with a color index of .8; the white count was 18,400. The differential count showed a peculiar picture of the blood; there were a moderate number of eosinophiles; the red cells showed a poikilocytosis, or much deformity, and there were a large number of nucleated red cells present. It was first suggested by Dr. Janeway that the blood appearances pointed to a pseudoleukemic condition of infants (anæmia infantum pseudoleukæmica of von Jaksch). The examination of the blood now, *i.e.* one year later, showed red cells, 3,100,000; hemoglobin, 43 per cent., with a color index of .7; leucocytes, about 16,000. In testing the coagulability with the newly-devised instrument he found that fibrin formation started after two and a half minutes at 72 degrees; when compared with the coagulability of the normal blood it showed an increase. He then sketched the appearance of the blood and called attention to one very peculiar cell, which was sausage shaped. To-day there were no myelocytes, and the eosinophiles were practically absent. There was a 72 per cent. polymorphonuclear count, 26 per cent. lymphocytes, 2 per cent. mononuclears and transitional forms of Ehrlich. The picture to-day, he thought, somewhat resembled a myelogenous leukemia. A true leukemia could be excluded. He called attention to the high color index in pernicious anemia; in the case presented there was a low-color index. None of the characteristic features of malaria had been found in the blood.

Dr. HENRY HEIMAN thought that the condition of the blood indicated a splenomyelogenous leukemia. In chronic leukemias the blood presented all kinds of changes.

Dr. GOLDHORN said that it could not possibly be a case of splenomyelogenous leukemia. The percentage of myelocytes was not more than two, three, or four.

A Case of Syphilitic Pseudoparalysis.—Dr. JACOB SOBEL presented this paper. He said that the osseous changes common to hereditary syphilis were most commonly manifested in the form of a diaphysoepiphyseal lesion; that is, an osteochondritis of the femur, humerus, tibia, radius, or ulna. This manifestation, when associated with other signs of congenital lues admitted as a rule of ready diagnosis, but when present as an initial symptom, so to say, it rendered a diagnosis not only very difficult, but at times impossible for a certain period. The following was a case in point: Helen Z——, age three weeks, bottle fed since birth, who had been brought to his dispensary service at Lebanon Hospital on December 1, 1904, with the history that for the past four days the child did not seem able to move its left arm. The child was apparently well until four days ago, when some friends who were visiting played with her and pulled the arm, as the guardian thought. The patient was the first born and the labor was normal, and, so far as the guardian knew, the parents were healthy. At the first visit the speaker and his associate paid particular attention to the examination of the left upper extremity, examining carefully the clavicle, shoulder, elbow, wrist, and hand; no subluxation was found, no fracture, no dislocation, and no swelling of any kind. There was, however, a drop wrist, with its characteristic deformity and disability. Tickling of the palm caused slight movement of the fingers. No callus pressing on the musculospiral nerve could be detected, nor was there pain on pressure over any of the joints. In addition to the wrist drop, there was a slight inward rotation of the arm, suggesting the upper arm type of birth paralysis, but the fact that the condition had appeared during the third week of life, and that there was no atrophy, ruled out Erb's paralysis. A physical examination of the patient at this time was absolutely negative, not even a palpable liver or spleen. A tentative diagnosis of traumatic neuritis was then made, and gentle massage with cocoa butter and rest were ordered. The guardian returned on two subsequent occasions, two and three days apart, to report some improvement at both times. Examination of the extremity, and especially of the wrist joint, revealed nothing except some slight pain on passive movement. All other joints were free and painless, and the gums were normal. There were no evidences of rickets. On December 10 there was detected a distinct crepitation at the lower end of the radius and ulna, at the junction of the epiphysis and diaphysis, an epiphyseal separation. The case was then transferred to the surgical service. One week later the face was covered partially with a papulopustular eruption, with adherent crusts here and there, especially around the mouth; the crusts resembled those of impetigo contagiosa, but were easily differentiated by their situation upon a copper colored base; the body showed a maculopapular ham colored eruption, and the skin of the soles and palms was desquamating and thickening; there were decided coryza, snuffles, mouth breathing, fissured lips; in a word, the clinical picture of congenital lues. The spleen and liver at this time were distinctly palpable. Then the diagnosis of the original condition became clear, of course, and the cause for the pseudoparalysis became evident. Subsequently distinct anal condylomata made their appearance. The forearm was immobilized with lateral splints, and the lues was treated in the dermatological service of the hospital by the administration of calomel, 1-20 to 1-10 grain doses three times daily, and by the twice daily application to the umbilical region of a pea-sized piece of white precipitate ointment, covered with a flannel abdominal band. In three and a half weeks no false point of motion or crepitation was detected, and in four and a half weeks the surgical aspect of the case was closed. Under the specific treatment rapid improvement was

made. It seemed that the sequence of events in this case—pseudoparalysis (epiphysitis), epiphyseal separation, and, lastly, the cutaneous outbreak—was interesting and instructive, and warned us to be on our guard in diagnosticating monoarticular involvements in young children. He said that, when brought face to face with a similar case in the future, after excluding trauma, fracture, sepsis, perhaps infantile scurvy, it might be well to turn one's thoughts to the possibility of osteochondritis epiphysaria luetica neonatorum.

Dr. HERRMAN said that the child showed no symptoms of syphilis, not even snuffles. Pseudoparalysis might result from traumatism, and there was a history of traumatism in this case. The pseudoparalysis usually affected the upper extremities, because the tendons of muscles were attached near the epiphyses in the upper extremity, which was not the case in the lower extremity.

Dr. L. E. LA FÉTRA had seen two cases of pseudoparalysis during the past year, in one of which an epiphyseal separation had been allowed to go on until the bones had assumed a very faulty position, both wrists being at right angles to the forearm; in the second case the lower extremity was involved, as well as the upper.

A Case of Visceral Syphilis in a Boy, with Heredo-Syphilis Lata.—Dr. SARA WELT-KAKELS presented a boy, nine and a half years old, who was the youngest of five children. The four elder children were all healthy. The father was said to have contracted lues two years prior to the birth of the patient. The child was born not quite at full term, was very small, and had to be wrapped in cotton for the first two weeks of his life. He also lost much blood through the slipping of a ligature around the cord. Soon he began to suffer from snuffles. When six months old there appeared swelling of the bones around the right elbow joint, which was supposed to be due to rachitis. There were also an umbilical and two inguinal hernias. When he was one year old he had a luxation of the right shoulder. When two years old he had an attack of measles, with complicating pneumonia and croup. In his fourth year he suffered from paronychia on the right great toe, which required a few months to cure. When six years old he began to suffer from an interstitial keratitis in both eyes, for which he was treated for more than a year. He was brought to Dr. Welt-Kakels for treatment for enlarged lymphatic glands of the neck two years ago. The patient suffered last summer from bronchitis, and never had eruptions on the skin. Five weeks ago he complained of abdominal pain, had no appetite, was constipated, and tired easily. The boy was found to be badly nourished, weighed thirty-six pounds, rather undersized for his age, skin pale and sallow, no icterus, upper median incisors notched, slight enlargement of the cervical, inguinal, and epitrochlear glands. There was a slight systolic murmur, most likely anemic in origin. The abdomen was considerably enlarged, the abdominal veins, particularly on the right, much dilated, with slight dullness in the lateral portions of the lower half of the abdomen, and a wave of fluctuation could be obtained. The liver was very large, mainly the left lobe, and was not sensitive on pressure, rather hard and resistant on touch, the upper border being in the right mammary line at the fifth rib, the lower margin of the right lobe ending about two inches below the free border of the ribs, while the lower edge of the left lobe was distinctly palpable some distance below the umbilicus. The extent of liver dullness over the left lobe was five and a half inches. The spleen was much enlarged, and its dullness joined the hepatic dullness; it extended about three inches below the free border of the ribs, was not sensitive, and gave a feeling of resistance; its surface was smooth. The urine was normal. The erythrocytic count was 4,480,000, and leucocytes 11,000, hemoglobin only 30 per cent. Nothing abnormal was found in the differential white count.

The Digestions of Caseins, and Its Relation to Certain Problems in Infant Feeding.—Dr. THOMAS S. SOUTHWORTH read this paper. (See page 321.)

Dr. HENRY DWIGHT CHAPIN said that it was generally recognized that percentage feeding was an important advance in the feeding of infants, inasmuch as it gave us the nutritive values of foods. He started in studying milk from a biological standpoint, studying the digestion of milk in different species of animals. He considered the work of the Department of Agriculture in the study of cows' milk to be very valuable. He thought that we should know more about the proteids of milk, where best digested, and how to prepare them for digestion, and the varying conditions which aided their digestion in different places. He thought that the proteids of milk had other functions than those of mere nutrition; that they were developmental as well. They aided in developing the digestive tract and preparing it for future foods. The addition of alkali to cows' milk simply changed its place of digestion from the stomach to the intestine.

Dr. WALTER LESTER CARR said that it was generally accepted that cows' milk was the best artificial food for infants. He compared the diamond and coal, both of which had the same composition, and yet were entirely different; the same comparison could be applied to cows' milk and mothers' milk. It was interesting to note what slight modifications occurred in milk from certain diseases, as influenza, for instance. More attention should be paid to the digestive strength of the child; a modification made upon a chemical basis could not be considered as important as this. The question was not so much whether the percentage conformed to the average percentage to be given the child of a certain age, as whether the percentage was one which brought the infant up to best point of development.

Dr. FLOYD M. CRANDALL said that he thought that the general practitioner was inclined to feed too large percentages, especially of proteids, while the specialist was apt to make this percentage too weak. What had been said regarding the saturation of the curd by acid tended to explain some of the difficulties encountered; children seemed to do better upon stronger than upon weaker mixtures. Often a child fed on a diluted mixture would pass a very tough curd; sometimes this was corrected by increasing the time taken in feeding, and also by care lest the orifice of the nipple be too large.

Dr. CHARLES G. KERLEY said that more attention should be paid to where the milk landed, its receptacle, and the condition of the child. He thought that it was better to get at the baby first, and to find out what was wrong with it. In cases of malnutrition he had found that daily washing of the infant's stomach was of great value. This aided in producing a good proteid digestive capacity. It was surprising how much mucus, fermented material, and bacteria could be washed out of this organ, which would not be expelled by vomiting. The general management of the child was very important. Plenty of fresh air, salt baths, general massage, and inunctions of oil were important aids. His advice was to treat the child rather than the milk.

Dr. G. R. PISEK thought that the use of alkalies would result in neutralizing the acid present in the milk, if we started out with the presumption that the milk was wholesome. The curd was not usually broken up by this means, but expelled into the intestines. If 2½ grains of bicarbonate of sodium were added to the ounce of milk, one would be giving two and one-half times as much as would be necessary to neutralize the milk if it was absolutely sour.

Dr. EDWARD F. BRUSH of Mount Vernon thought that, although much honest work had been done along the lines of infant feeding, if good results were to be obtained, we were on the wrong track. In speaking of the chemistry of milk, most men spoke as they would of 90 per cent. of alcohol, as though it was always the same. This was not true of milk. When the lactometer was used, its object could be defeated by adding burnt sugar to the milk, which raised the specific gravity. If the percentage of fat was too low, they added water; if germs were present, it was

found that the centrifugal machine, used slowly, could dispose of them. The work of the New York Board of Health in visiting the dairies was of the greatest value. A visit to some of these farms would account for the many failures to modify milk satisfactorily. If the farmer was compelled to keep his places clean and to keep preservatives from the milk, so many attempts at modification would not be necessary.

Dr. Elias H. Bartley of Brooklyn said that if the calcium salts were removed from the milk, it would pass through the stomach without curdling, provided there were no calcium salts in the stomach. Most substances added to prevent curdling were injurious to the child.

Dr. Thomas S. Southworth summed up the matter by saying that it was better to understand the physical changes occurring in the milk than the chemical. A child to have good digestion must have good physical condition. Dr. Kerley's success in infant feeding was possibly due to the fact that he gave the weaker mixtures first, and then he was able to give the stronger.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held February 20, 1905.

The President, Dr. Francis J. Quinlan, in the Chair.

A Memorial to Dr. M. L. Maduro.—Dr. Emil Mayer presented this memorial to the Association.

Alcohol in Health.—Professor Russell H. Chittenden of Yale University read this paper. He said the question was often raised, Does alcohol in moderate quantities serve as a food? There was no question but that alcohol could be oxidized in the body and energy made available for the requirements of the system, but it was not always to be recommended for food. When introduced in large quantities alcohol was excreted through the lungs, the skin, and the kidneys, which showed that the body could not handle large quantities; at the same time aldehydes and acetic acid products were formed, which indicated an incomplete breaking up of foodstuffs. He asked what a moderate quantity of alcohol was, and then quoted largely from the results of Goddert's experiments on dogs, published in *The Lancet*. An animal weighing 160 pounds could oxidize 84 grams of absolute alcohol. The strongest whiskey contained about 50 per cent. alcohol, and, therefore, this would represent about 168 grams of pure whiskey. In the experiments absolute alcohol was given, diluted in equal parts of water. In other words, it was shown that a healthy man, weighing 160 pounds, was capable of oxidizing 168 grams of pure whiskey. Such an amount of whiskey taken at one time would produce very uncomfortable results, but it showed that this amount of alcohol could be oxidized in the body and serve as a food. But it should be borne in mind that the animals used in these experiments were dogs, and in a fasting condition, or in a semi-hungry state. Still, it went to show that animals were capable of using a fairly large amount of alcoholic drinks. A man weighing 160 pounds could completely oxidize the alcohol contained in a quart of port wine. The general conclusions were in accord with the experiments of Prof. Atwater, who showed that 72 grams of absolute alcohol were oxidized in a day completely. Dr. Atwater found that 98 per cent. of that was burned or oxidized, proving that it had been utilized as a food. Foods had been found to serve the purpose of assisting in building up and repairing the tissues of the body and yielding energy. For the building up of muscles proteids were necessary, but the oxidizing of the carbohydrates was the chief reliance of the body for sources of energy. Alcohol had long been recognized as being capable of stimulating metabolism. Prof. Chittenden then dealt with certain facts regarding alcohol in metabolism, which tended to differentiate alcohol as a food still more sharply. Eighteen years ago experiments were carried on to show the influence of alcohol upon proteid metabolism in dogs, and a study of its influence as a foodstuff. It was then observed that there was no output of uric acid in these animals; the total output of nitrogen was diminished. Dr. Beebe's experiments upon man gave results which had a very important bearing upon the question. He took five young men who were in particularly good health, and none of whom was accustomed to the use of alcohol, and his results showed that alcohol, even in moderate amounts, caused a noticeable increase in the amount of uric acid and purin bodies in the urine. The increase of uric acid in the urine was not of endogenous origin, but was associated with a change in oxidizing power, exogenous possibly, or associated with some change in connection with the production of uric acid from some of its precursors in the food. He concluded that alcohol, being absorbed, reached the liver and influenced metabolism, by which some cleavage product was made, bringing down some nuclein compounds. The observations of Beebe showed that certain alcoholic drinks, as port wine, exerted a greater influence upon the uric acid than a corresponding amount of alcohol would, and this suggested that the moderate drinking of alcohol might be attended by metabolic disturbances in the body, more than people believed. The deleterious influence of alcohol, or alcoholic drinks, was observable only in cases accompanied by an exogenous output of uric acid. In disease, however, alcohol ingested was not followed by an increase in the output of uric acid. Alcohol, therefore, he said, could not be looked upon as a true food.

Alcohol in Disease.—Dr. George L. Peabody said that very little of the recent work by scientists related to alcohol except as a food, and he would speak of its use as a therapeutic agent in disease. He spoke of its use in angiomata, in carcinomata, and as a disinfectant of the skin, because of its powers of permeation. Alcohol had been applied to the abdomen on compresses soaked in it in cases of peritonitis. Dr. Peabody had found it very efficacious in peripheral neuritis and phlebitis, as well as in abscesses, such as furuncles and allied conditions, but to be effective it should be applied early. It was also of value in phlegmonous inflammations. Its power of relief was best explained by its powers of dilating the blood-vessels and relieving conditions of pressure. The alcohol was used by soaking cheesecloth compresses, applying them to the parts, and covering with gutta-percha paper and cotton wool. The compresses should be saturated. This should be used cautiously in cases in which the epidermis was very thin. Neither should it be applied to the scrotum or in children unless well diluted. Its antidotal powers in cases of carbolic acid poisoning were referred to. During recent years, he said, the tendency was to recede from a very great use of alcohol as a therapeutic agent, and many physicians refused to use it in any cases. It was a fact already proven that large doses of alcohol rendered animals less resistant to pathological conditions. Dr. Peabody believed that in alcohol we possessed the best means of stimulating the heart. Necessity for its use might arise from some primary weakness and enfeeblement due to febrile diseases. Often this agent was prescribed when not justified. The use of alcohol should not be abandoned because of the fact that it was much abused. The symptoms of intoxication, he said, were due to its paretic effect upon the cerebral cortex. When all was said against alcohol, it still remained that it had a place in its general applicability. In cases of high, persistent temperature, with delirium, nervous prostration, with a pulse rapid and easily compressible and dicrotic or irregular, this condition always called for the administration of alcohol. Its dose should be half an ounce of whiskey every three, four, or five hours to begin with, but its continuation should stop as soon as it no longer was productive of good. When the patient approached the condition of health, he cautioned against its habitual use. When the tongue became less dry, and the skin moist, when the wakefulness and delirium became less marked, and when the powers of assimilation improved, then the further giving of alcohol should cease.

He subscribed to Meltzer's saying, that "Alcohol in health was often a curse; alcohol in disease was mostly a blessing."

Wood Alcohol.—Mr. J. P. Atchinson, Chemist to the New York Board of Health, read this paper, which considered the methods of manufacturing wood alcohol, and the various ways by which it could be detected when used as an adulterant.

Legislative Aspects of Alcohol.—Hon. Maynard Y. Clements, New York State Deputy Commissioner of Excise, read this paper, and said that since the Whiskey Insurrection, or Rebellion, in 1794, there had been no peace between the Excise Law and the Excise Commissioners. Students of criminology and statesmen of large experience all recognized the fact that the liquor traffic was not only dangerous, but that it caused from 75 per cent. to 90 per cent. of all crimes committed. This overwhelming mass of evidence could be sustained by looking over the prison dockets of city and State. In dealing with the liquor problem, he said, they were dealing with the friend of crime, and not with the personal liberty of citizens. In 1896 radical changes were made in excise laws of the State and city. Theodore Roosevelt, as Police Commissioner of the City of New York, in spite of the fact that the new law was drawn up by Tammany legislatures, saw that the law was enforced. "The power to tax is the power to destroy," and taxing the liquor business he said was only taxing that which gave rise to so much that was evil. The Raines law tried to deal fairly with the liquor interests and with the taxpayers. With the old law less than three millions was raised by taxation; the Raines law raised eighteen millions, one-half of which went to the State for the reduction of taxes, for State purposes, etc. Up to September 30, 1904, the Raines law had produced since 1896, $121,736,687.71; of this amount $54,000,000 was collected in the old county of New York. The excise tax was against the liquor dealers, and not against the city of New York. On April 30, 1904, the excise tax received was $7,727,000; this was $2,673,000 more than had ever been received when the old law was in force. Not only were the results gratifying as revenue, but it was a fact that there had been a large number of saloons put out of business. There had also been noted a large decrease in the number of commitments because of intoxication, a reduction of 39.5 per cent. He referred to the "frenzied" law of 1892 with its ten-room provision; the proper enforcement of the building code of this city he said would close every ten-room Raines law hotel in the city. No relief could be expected from amendments but from the good character and conduct of public servants who had been tried and had not been found wanting. To-day it was a question *not* of the measure, but of the man. Only in honest public service rather than any public measure lay the solution. The law itself was merely the instrument or the tool and everything depended upon the workman who employed it. If a workman was dishonest, a change of tool would not help. He did not believe that any Sunday opening of saloons would be much of an expedient except that it gave greatest liberty to the worst trade. He asked if it was intended to correct a bad condition by a bad remedy? It would seem far better that the police service, which under home rule was a hopeless failure, should be made more perfect by a State constabulary.

Substitutes for Alcohol.—Dr. Charles B. Fitzpatrick read this paper in which he called attention to the medical, the natural, and the artificial substitutes for alcohol in disease as well as in health. Defective means of determining its right use was accountable for the abuse of it. Non-alcoholic substitutes should be advised and then he believed people would lead much happier and more useful lives. The substitute for alcohol should be in the form of drinks which would not interfere with the assimilation of fats and hydrocarbons. A good active digestion was very much needed, and alcohol interfered with this, especially cell digestion. Alcohol rendered the blood more susceptible to the toxic influences of infections. The best substitute for alcohol he believed to be good, fresh, clean drinking water, which should be taken in sufficient quantities to satisfy the thirst. He believed it would be a wise thing to have different water supplies, one for drinking purposes. Bacterial toxins should be diluted as much as possible without injury to the patient and, in such cases, water was of the greatest value. The substitutes for alcohol in various diseases were mentioned.

Dr. Graham Lusk spoke of Dr. Mandel's experiments with a patient in the laboratory, covering a period of two weeks. This man took 900 c.c. of whiskey to cover the daily needs of the body; he preferred to take clear whiskey and no other food. With difficulty he was persuaded to starve and give up the whiskey also. The results of the experiments showed that the amount of uric acid eliminated in the urine was about the same whether the man was taking 900 c.c. of whiskey or not. This showed that the endogenous production of uric acid was not affected. If alcohol was fed with the food, it was shown that uric acid would be increased; that included exogenous as well as endogenous production. Under these circumstances, if alcohol be ingested, and particularly port wine, the amount of uric acid might rise from 0.5 gram as high as 0.8 gram; that represented an increased output of 40 per cent. under the influence of port wine, but Dr. Lusk said it was even higher than that. He differed with Dr. Chittenden when he stated that the oxidizing power of the liver was reduced; its oxidizing power as well as that of the tissues was usually quite the same as long as life persisted. It might be that the alcohol damaged the ferments which came from exogenous sources. In diabetes, for instance, there was some damage to the ferment which caused the trouble, and the same might be said of alcohol in this connection.

Dr. Thomas D. Crothers of Hartford, Conn., said that the study of the alcoholic problem dated back thousands of years, but in 1870 the first society was formed for the study of inebriety; to-day the number of medical men who were devoting time to the study of this subject was less than 200. This was in striking contrast to the reform movements, more than one million in associations, societies, and clubs being engaged in curing the evils from this source. Their work was based on the theory that alcohol was a moral evil. He wished to emphasize the fact that alcoholism was in truth a neurosis and amenable to treatment. There were two forms to be considered clinically; first, that marked by delusions of strength to control and the extreme confidence in the capacity to drink or to abstain; secondly, that form with convulsions of epileptoid character which occurred periodically—veritable drink storms. But a few years ago there were hundreds of institutions in this country for the care of these patients, and they gained much by working upon the credulity of these individuals who seemed ever ready to accept all sorts of theories. The great practical question now was why should this evil be studied almost entirely by laymen? Exact scientific means should be adopted in the treatment of inebriates to-day. The alcoholic problem, he said, should be taken up and studied in the same way that one did typhoid fever or tuberculosis, and the public should be taught the exact means of prevention and cure.

Hon. De Lancey Nicoll said he had intended to speak on the Raines law but after the admirable defense of it by Mr. Clement he had changed his mind. He said that ever since man existed he had been engaged in making some kind of alcohol out of some kind of material, trying to find the fluid that cheers and sometimes inebriates. During this time there had been several epochs in which abstinence held the sway and others in which alcohol. One hundred years ago alcohol came into complete possession of the field. Years ago in the United Kingdom a man who did not drink alcohol was viewed with suspicion; he could not serve on the jury unless he drank alcohol; he could not act as executor or trustee unless he occasionally took a drink. Even life insurance companies would not insure a man who was a total abstainer. Seventy-five years

ago he said the total abstainers were obliged to form a life insurance company of their own in order to convince those who drank no alcohol that their chances of life were just as great as those who drank. To-day they had reached the time when it was held that total abstainers had as good a chance. Mr. Nicoll said he had supposed the consumption of liquor in the United States was growing less, but he found that it was growing greater every year. Last year there were one thousand million gallons consumed, exceeding the amount consumed the year previous by about one hundred millions. In New York City, though, not much more was taken than was consumed twenty-five years ago. He said that in clubs to-day one seldom saw an intoxicated man, but this was not the case twenty-five or fifty years ago. He believed that temperance was growing and would continue to grow. He cautioned against the teaching that alcohol was a food because some might prefer to live on it. Few men knew how to use alcohol in moderation. He said he knew of no solution of the problem except teaching men the pleasures and benefits of temperance and convincing them that the chances of their living prosperous and happy lives were very few if they continued the over-indulgence in alcohol.

Dr. MASON asked what a moderate dose of alcohol was. He did not believe there was any arbitrary rule to be offered because every man was a law unto himself; constitutional idiosyncrasy should be taken into account. Dr. Mason had made a special study of alcohol since 1866, and during that time had treated between four and five thousand inebriates and he believed that alcohol was the greatest disease producer the world ever saw and was one of the greatest factors in filling the insane asylums. He asked what the status of the inebriate was, whether he was a criminal or a degenerate. The law now regarded him as an irresponsible individual; if so laws should be made for his control.

Coroner's Bill.—Dr. THOMAS J. HARRIS moved that the New York County Medical Association endorse the Coroner's bill, which had for its purpose the object of abolishing the coroners in the city of New York. This was unanimously carried.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

AT a stated meeting of the Section on General Medicine held February 13, Dr. A. O. J. KELLY exhibited "A Patient Recovered from Pyopneumothorax after Spontaneous Evacuation through a Bronchus." The case occurred in a hardy man who had been sick for a week before coming under observation, when he presented physical signs indicative of a moderate pleural effusion. His condition gradually grew worse, but considerable relief followed the discharge from the mouth of a large amount of pus. Puncture now disclosed the presence of pus in the pleural cavity, and accordingly a portion of a rib was excised, the purulent accumulation evacuated and drainage provided for. Recovery eventually took place, in spite of the desperate condition of the patient. Dr. AUGUSTUS A. ESHNER presented "A Patient with Aortic Obstruction and Insufficiency and a Loud Diastolic Musical Murmur." The case occurred in a colored man, 32 years old, who complained of palpitation of the heart and dyspnea on exertion. He gave a history of rheumatism, but denied venereal infection. The physical signs referable to the heart were extraordinary. The apex-beat was greatly increased in extent and displaced to the left. The area of cardiac dulness was augmented. Pulsation was visible in the epigastrium, and in the vessels above and in the subclavian below the clavicle. A distinct thrill was palpable over the precordia and in the neck, and it presented both systolic and diastolic elements. On auscultation a loud, rough systolic murmur was audible, followed by an even more loud musical diastolic murmur. These could be heard over all parts of the chest and they were transmitted into the peripheral vessels down to the radial and the abdominal aorta to the bifurcation. They were not audible in the femoral or dorsalis pedis, although a distinct shock was appreciable in these vessels on both ausculation and palpation. The diastolic murmur could be heard at a distance of six inches from the chest. At the apex there was also a presystolic murmur followed by a systolic shock. The pulse was quick, and sharp, but unsustained and receding. Sphygmographic tracings exhibited a high and vertical upstroke and a sharp and rapid descent, with a marked recoil elevation and a slight but elongated elasticity elevation. Capillary pulsation was also visible. Dr. Eshner also reported "A Case of Universal Congenital Atrichia." The patient was a man, 64 years old, who had not a trace of hair on any part of his body, and, according to his own statement, never had had any. The nails of the fingers and toes were imperfectly developed and rugous. The teeth had gradually fallen out. Perspiration was moderate. There was no family history of similar disorder. The rare anomaly of retinitis albicans also was present. The term atrichia was preferred to describe the condition, on the belief that there had been a defect in the development of the hairs, while alopecia or baldness would imply the loss of hair that had once been present. Brief references to cases of similar character were found in the literature, but none had been described in length. The disorder is to be looked upon as a dystrophy, and is to be referred to failure on the part of the permanent hair to replace the lanugo when this falls out in intrauterine existence. It may bear some relation to the antithetic disorder of hypertrichia, observed in so-called hairy men, in which the lanugo fails to fall out, but grows to an inordinate length. Histologic studies in some cases disclosed a condition of deficiency or absence of hair-follicles. Changes in the nails, teeth, skin, and perspiration, as well as other dystrophic conditions, are often found associated. Drs. SAILER, GEISLER, and WELTY read a paper entitled "Polycythemia with Cyanosis, with a Report of Three Cases." One of the patients was a child of eight years, and in another the spleen was not enlarged. Death occurred in the former and the heart was found normal on post-mortem examination except for a slight degree of endocarditis involving the mitral valve. Only a small number of cases of the kind have been placed on record. The extremities and peripheral portions of the body are cyanotic. The number of red blood cells is greatly increased, as is also the percentage of hemaglobin. As a rule the spleen is enlarged. The condition appears to bear certain analogies to splenic anemia. Dr. J. NORMAN HENRY read a paper entitled "Paratyphoid Fever, with a Report of Six Cases." He described the bacteriology of this disorder and discussed its symptomatology and the differential diagnosis, with respect especially to typhoid fever. Dr. THOMAS L. COLEY read a paper entitled "Diet in Typhoid Fever."

THE PATHOLOGICAL SOCIETY OF PHILADELPHIA.

AT a stated meeting held February 9, Dr. W. M. L. COPLIN presented "Specimens from Three Cases of Hemorrhagic Pancreatitis." One came from an infant with syphilitic heredity, and the lesions were rather sclerosing in character, with only a moderate extravasation of blood. The other exhibited two stages of hemorrhage, an early and a late. In the third symptoms of intestinal obstruction were present during life, but a diagnosis of hemorrhagic pancreatitis had been made. Death occurred, however, before surgical intervention could be undertaken. In each instance fat necrosis was present in omentum and mesentery. Dr. A. O. J. Kelly exhibited "Specimens from a Case of Hemorrhagic Pancreatitis." The patient presented symptoms of intestinal obstruction, for the relief of which operation was undertaken. Dr. J. H. MUSSER presented a "Specimen of Carcinoma of the Pancreas." The primary lesion had evidently been at the ileocecal valve. Dr. Musser presented also a "Specimen of Duodenal Ulcer and Cirrhosis of the Liver." The ulceration of the duodenum had been recognized during life, and operation was undertaken for the relief of the hemorrhage. The condition of the liver was now discovered, and the bleeding was furious. Death resulted a day later. Dr. Musser exhibited further a "Specimen of Ulcer-

ative Endocarditis." The condition was grafted upon a chronic mitral valvulitis, and during life there had been recurrent pyrexial periods. Dr. Musser exhibited finally a "Specimen of Carcinoma of the Stomach and Peritonitis." The peritonitis had developed apparently without perforation. Drs. J. FUNKE and S. SOLIS COHEN presented a communication entitled "Syphilis of the Liver—Sclerogummatous Type." Dr. H. R. M. LANDIS presented a communication entitled "Tuberculosis of the Liver," and he exhibited illustrative specimens. He contended that the condition must be more common than it appears to be, the tubercles being demonstrable microscopically often when not evident macroscopically. Dr. D. J. MCCARTHY exhibited "Two specimens of Internal Hydrocephalus." One came from a patient with a neoplasm of the cerebellum, exerting pressure on the aqueduct of Sylvius, and in this way interfering with the circulation of the cerebrospinal fluid and its retention within the ventricles. The second specimen was somewhat similar in character, although relief to the symptoms had on several occasions been afforded by opening the skull and excising a portion of the cerebellum. The patient was a tuberculous child, and it was accordingly thought a tuberculoma of the cerebellum was present. The symptoms in cases like that in question were principally headache, disturbances of gait, abolition of the knee-jerks, vomiting, and optic neuritis—essentially those of cerebellar tumor, but without localizing indications. D. J. FUNKE exhibited a "Specimen of Vegetative Endocarditis," involving the mitral leaflets in marked degree, but even more conspicuously the lining of the left auricle.

New Instruments.

SPECIAL INSTRUMENTS FOR FACIOHYPOGLOSSAL NERVE ANASTOMOSIS.

BY ALFRED S. TAYLOR, M D.

NEW YORK.

IN the three cases of anastomosis reported a year ago by A. S. Taylor and L. P. Clark (MEDICAL RECORD, Feb. 4, 1904), a number of difficulties were encountered during the operative procedure: (1) The downward projection of the auditory process of the temporal bone diminished the length of facial nerve obtainable by means of a straight knife. When this nerve stump is too short, its approximation to the hypoglossal is difficult, and there will be undesirable tension on the sutures; (2) ordinary scalpels are so clumsy as to do unnecessary damage in making the lateral slit in the hypoglossal nerve; (3) to pass the sutures through the sides of the slit in the hypoglossal with an ordinary needle and holder was not only exceedingly difficult, but resulted in such pulling about and traumatism to the nerve as to cause a well-marked paralysis of its muscles, lasting for weeks. At first the difficulty in speaking and swallowing was most annoying,

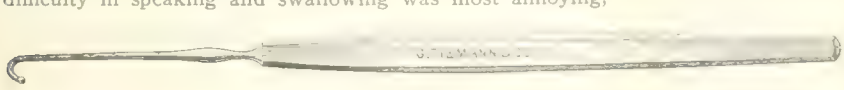

Fig. 1.

but slowly disappeared with the recovery of the nerve.

With the hope of rendering the operation easier technically, and more precise anatomically, and of avoiding the distressing sequelæ above mentioned, the instruments set forth in this paper were designed. I have to thank Geo. Tiemann & Co. for their skill in making them as well as their many courtesies during the experimental stage

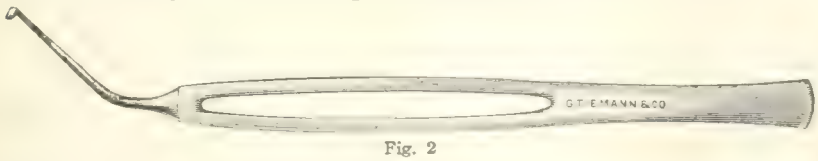

Fig. 2

of the work.

The hook (Fig. 1) is designed to hold the facial nerve tense while it is being divided at the stylomastoid foramen, as well as to support the hypoglossal while the lateral slit is being made and the sutures passed. With an instrument of this sort the nerves can be controlled and manipulated with the minimum of traumatism.

With the angular knife (Fig. 2) it is a simple matter to reach up along the trunk of the facial nerve, and divide it at or just within the stylomastoid foramen. The angle is such as to favor the easy insertion of the shank of the knife beneath the auditory process of the temporal bone.

By means of this knife one may obtain fr[illegible] ½

Fig. 3.

inch more of nerve than can be gotten with any straight instrument.

The double-edged narrow bladed eye-knife (Fig. 3) is admirably adapted to making the lateral slit in the hypoglossal while it is supported on the hook (Fig. 1). The needles (Fig. 4) are right and left for convenience. The curve of the needle and the angle of its attachment to the shank adapt it nicely to the passage of sutures in the hypoglossal without disturbing it as it lies at the bottom of the deep, narrow wound.

The eye is sufficiently large to carry No. 2 silk though that size is threaded with some difficulty. No. 00 is sufficiently strong for this anastomosis, as there is no tension placed upon the suture. The needles are spear-pointed to permit sufficient eyehole, but the point is thin, and as it should pierce only the nerve sheath of the twelfth

Fig. 4.

cannot do material damage. These needles may be used for nerve suture in other regions when No. 2 is sufficiently strong.

In Case IV, operated upon January 7, 1905, these instruments were used, approximation of the nerves was easy, and the traumatism to the hypoglosssal was so slight that there was no subsequent paralysis of its function.

Case VI of the series was most difficult because of a very large prominent transverse process of the atlas, which placed the dissection of the hyperglossal nerve in a very narrow, deep hole. Had it not been for these instruments, especially the angular needles, the operation could not have been completed without transverse section of the hypoglossal, followed by end to end suture with the facial or resort to the spinal accessory nerve, neither of which procedures is so desirable, in my opinion, as the operation previously referred to.

In this case, although considerable manipulation of the hypoglossal was necessary, the resulting loss of function was slight. On the second day the tongue could be protruded and moved in every direction.

152 WEST FIFTY-SEVENTH STREET.

Experimental Tuberculosis of the Heart and of the Aorta.—Léon Bernard and Salomon conclude that: (1) Extreme infection of the blood of the left ventricle, by Koch's bacillus can cause tuberculosis of the endocardium, and sometimes of the lining of the aorta, without previous lesions of the valves. (2) These primary tuberculous infections of the heart and of the aorta consist of granulations whose histological structure is identical with that of the common inflammatory lesions of these membranes. The reaction is fibrinous and not follicular, although bacillary. (3) This specialization in the endocardium is made clear when it is remembered that the same bacillus produces typical nodules in the other tissues of the heart—the myocardium—the subendocardial and subpericardial strata.—*Revue de Médecine*, January 10, 1905.

Photography of the Fundus Oculi.—Satisfactory photographs of the fundus oculi have, it is said, been taken by Dr. Walther Thorner. The subject looks into an instrument somewhat resembling the old-fashioned box stereoscope, and the eye being illuminated by a kerosene lamp, the image is cast on a ground glass screen. It is carefully focussed, and the screen replaced by a sensitized plate. Simultaneously with the pressure of the shutter, an electric spark ignites some flashlight powder. In an article in the *Scientific American* for December 17, illustrations of the apparatus and its modus operandi are given, and also five pictures of the fundus showing normal optic nerves, the yellow spot, the optic nerve of a myope, and an eye affected with choroiditis. Dr. Thorner has devoted many years of patient labor to the accomplishment of this end, and while his method is not absolutely perfect, it has attained to a good working stage.—*St. Louis Medical Review.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 25, 1905:

	Cases.	Deaths.
Measles	292	5
Diphtheria and Croup	258	45
Scarlet Fever	261	14
Smallpox	5	1
Chickenpox	121	
Tuberculosis	318	164
Typhoid Fever	28	10
Cerebrospinal Meningitis		49
Typhus Fever		
Yellow Fever		
Cholera		
Totals	1,283	288

American Surgery Through French Eyes.—The following account of the impressions of a French visitor to this country is taken from *The Medical Press and Circular*. Dr. Faure, the well-known Paris surgeon, has recently paid a visit to America, and on his return to France has published the result of his observations. He was particularly astonished at the magnificence of some of the operating rooms in the New World, and he mentions the Mount Sinai Hospital, New York, as the handsomest he has seen. Both walls and ceiling are formed of single sheets of white marble. The number of assistants and nurses present at an operation—three or four of each—is in contrast to what obtains in Franse, where the surgeon aims at performing his work with the aid of only one assistant. What claimed M. Faure's admiration more than anything else was the excellent and intelligent nursing across the Atlantic. The American nurse is usually a young woman of good education and social standing, quite different from the French *infirmière*, and tasks are entrusted to her which in Paris are the duty of the *internes*. American surgical instruments appeared clumsy and coarse to one used to the neatness of the hand-made articles in use in France. While M. Faure, like another observer, thinks that there are some matters they order better in France, yet he is, on the whole, an appreciative critic of American surgery.

A Surgical Dueling Sword.—A French surgeon of international reputation, whose assistance is always sought for at big duels, has invented a dueling sword, designed in conformity with anatomical principles. The handle is of remarkable design and is shaped to correspond with the impression of the fingers obtained by grasping a suitable cylinder of modeling clay. There is a special place for the thumb, preventing shock against the guard. It is asserted that the new sword prevents cramp.—*New York Herald.*

Canadian Vaccination Results.—A Canadian correspondent in the *Times* draws attention to a notable testimony in favor of vaccination. He states that twenty years ago smallpox was introduced into Montreal, where the French-Canadian population were for the most part unvaccinated. This visitation carried off upwards of 3,000 victims. Since then the French inhabitants in Montreal have accepted vaccination, and, although the population has grown largely, only 38 deaths are recorded from smallpox since the disastrous outbreak of 1885.—*The Hospital.*

Pseudonyms of Syphilis.—Some interesting information is brought together by Dr. Knott, in the current number of the Dublin *Journal of Medical Science*, with regard to the early history of the disease and the word "syphilis." He tells us that the word was first used in 1530 as the title of a poem by Hieronimo Fracastorio, a native of Verona. This astonishing poem, which describes what was then thought to be a new disease, fills a quarto book of thirty-six leaves, and is highly praised by many critics from Scaliger to Dr. Knott himself. The latter is not a believer in the doctrine that syphilis was first introduced to Europe by the sailors of Columbus, and he brings much evidence to show that it existed long before, though there is no doubt, of course, that its great prevalence in modern society dates from the Siege of Naples in 1494. From its devastation of the French army at that time it obtained the well-known name *"morbus gallicus,"* though the French themselves called it *"morbus neopolitanus."* Indeed, there were many national names given to it in different countries, as, for instance, "Spanish itch," "German," "Polish," "Turkish," disease, while the Turks responded with the name "Christian disease." From its similarity to the physical affliction of Job, it has been known as *"morbus sancti Jobi,"* and certain saints—St. Mevius, St. Roch, and St. Lementius—have also had the discredit of giving it a name.—*Medical Press.*

A Tuberculosis Museum.—Karlsruhe has followed the example of Charlottenburg in establishing a tuberculosis museum. Arrangements are being made by which parties of working people will be enabled to visit the museum from all parts of the country.—*Science.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the period from February 18 to February 25, 1905.

SMALLPOX—UNITED STATES

			CASES.	DEATHS.
Florida, Jacksonville	Feb.	11–18	4	
Illinois, Chicago	Feb.	11–18	15	4
Galesburg	Feb.	13–20	1

THE TREATMENT OF EPIDEMIC CEREBROSPINAL MENINGITIS BY DIPHTHERIA ANTITOXIN.

BY EDWARD WAITZFELDER, M.D.,

NEW YORK,

CONSULTING PHYSICIAN TO RANDALL'S ISLAND HOSPITALS; VISITING PHYSICIAN TO GOUVERNEUR HOSPITAL.

OF all the diseases we are called upon to treat, there is none with greater mortality or with more unfortunate and unhappy sequelæ than cerebrospinal meningitis. I have often thought that death was a much more satisfactory termination than the frequently occurring blindness, deafness, idiocy, paralysis, etc., which we see so often as a result of the disease. The mortality averaging seventy per cent. at the beginning of an epidemic, and never less than thirty per cent. in sporadic cases, is surely very discouraging, and it is probable that were statistics made from adult cases alone, these figures would be very much higher.

During the epidemic of 1873, I had the opportunity of seeing seventeen adult patients, all of whom died. The present epidemic, which began about the end of February, 1904 (just a year ago), has resulted in 1,010 deaths in this city. There were admitted during the year 1904, to Gouverneur Hospital, 113 cases, of which there were deaths 75, unimproved 5, improved 5, and cured 28. The cases at the beginning of the epidemic were usually of the fulminating type, requiring lumbar puncture for the relief of the pressure symptoms, and the fluid obtained from the series reported in this paper, with two exceptions showed the presence of *Diplococcus meningitidis intracellularis*. In one case (No. 10), the symptoms were not characteristic on admission, and lumbar puncture was resorted to because of the mental and occular symptoms and the suggestion of the Kernig's sign (that is, the inability to extend the leg when the thigh is flexed on the abdomen).

The virulence of the present epidemic seemed to abate somewhat during the summer and fall of the year 1904, so that when I came on service at Gouverneur Hospital, on November 1, 1904, the meningitis ward had in it only a number of old cases, presenting a picture so terrible that one would have thought that death would be a blessing to them. The duration of stay in the hospital was very long—in one case 183 days. So disheartening was the sight of this suffering that it might well be written over the entrance to the ward: "Who enters here leaves hope behind."

Early in January of this year, my attention having been called to the fact that Dr. ARTHUR J. WOLFF, bacteriologist of the Board of Health of the City of Hartford, Conn., had stated that he had found an antagonism existing between the Klebs-Loeffler bacillus and the diplococcus meningitidis, I requested my house physician to communicate with Dr. Wolff and ask for particulars, stating that I was ready and eager to try any plan of treatment which promised better results than we had been obtaining. The result was the following letter:

"Hartford, Conn., January 17, 1905.

"To Edwin A. Colton, M.D.,
"House Physician,
"Gouverneur Hospital, N. Y. City.

"Dear Doctor:—

"There is but little to say about the serum treatment of epidemic cerebrospinal meningitis, except that the few cases in which it has been tried here and in the surrounding towns, have recovered, and to remind you of the fact that I fully recognize that 'one swallow does not make a summer.' During the past ten months we have been investigating the diplococcus intracellularis meningitidis, carrying out cultures from the lumbar puncture fluids (almost all the cases we had here were diagnosed by means of the lumbar puncture). We early found that there is a pronounced antagonism between the Klebs-Lœffler bacillus and the meningococcus, and during the course of study on this portion of the investigation, I found that pure cultures of the meningococcus were killed by the antidiphtheritic serum, and not only precipitated when mixed with the latter, but active bouillon cultures, when mixed in bulk with the antitoxin, are precipitated in the same manner. The ubiquitous newspaper man got hold of the whole matter, ere we have had time to finish either our work or our paper, and the happy result has been the treatment of four cases of meningitis with the serum. All of these cases have recovered, one of them is not wholly well at the present writing, but is well on the road to perfect recovery, and you must draw your own conclusions as to the effectiveness of the treatment.

"I was called yesterday to see a little girl, 10 years old, who was seized with convulsions last Thursday. The attending physician told me that she had complained of headache, and suffered with several nose-bleeds during the past two weeks, and that she had complained of feeling very tired. Her convulsions began at 6.30 P. M. last Thursday, and continued until 10 P. M., and at the time he saw her the temperature was 109°; there was complete opisthotonos. This was all the history I could obtain, except that the temperature and pulse was reduced by cold sponging.

"When I saw her (five days later), she was completely unconscious, and impossible to rouse; there was left-sided hemiplegia; ptosis of the left lid; stiffness of the neck, well marked, the right pupil responded well to the light, while the left pupil was irresponsive. Respiration 32, pulse 102 and regular.

"Kernig's sign was present, well shown in both limbs. The abdomen retracted (perfect boat-shape). I drew about 30 c. c., of a very clear fluid, at the lumbar puncture, and the centrifugated deposit showed about an equal number of mononuclear and polymorphonuclear leucocytes; in the latter as well as in the free fluid the characteristic diplococci were found, which I am now studying in the different media. I gave this little girl 6,000 units under the scapulæ immediately after taking the fluid from the spinal canal.

"The doctor reports to me to-day that she is better, that she has roused and called for water; that her temperature and pulse are decidedly better, and that the picture to him is not nearly as desperate as it was yesterday.

"If this case comes along, I shall begin to think that we have in antitoxin a very powerful remedy for the treatment of the disease, but from what I have observed, both in the laboratory and from actual trial of the serum, I feel that we ought to give it an extensive and fair trial.

"You may ask me how it acts. I can only answer that we must make the theories fit the facts in this case, and not the facts the theories.

"If you see fit to try the antitoxin, use it as early as possible, and use a large dose, not less than 6,000 to 10,000 units. I have not the time at the present to go into all the particulars of our investigations, for we have a great deal of information, which will be given in our paper, but

one very important fact will be interesting to you. As the disease advances, the fluid taken from the punctures becomes more and more acid in reaction, and one can almost follow the course of the disease from this testing of the reaction.

"Hoping what I have given you may be of some use to you, and that you will give this method of treatment a fair trial, should you have the opportunity, I am,

"Yours very sincerely,

"ARTHUR J. WOLFF."

I need not say that I was impressed with so scientific, logical and withal so practical a statement, and I felt that it needed but clinical confirmation to demonstrate a serviceable discovery in medicine. Our treatment heretofore had been mainly symptomatic, the only departures from that being the injection into the spinal canal of some antiseptic or germicidal fluid or the hypodermic injection of bichloride of mercury along the spinal column. These, like all others, proved to be ineffectual.

A few days after the receipt of this letter, we received at Gouverneur Hospital the first patient of the recurrence of the epidemic, viz.:

CASE I.—J. B., aged 8 years was admitted January 20, 1905, with a history of two days' previous illness; headache, vomiting, and partial loss of consciousness; on admission, head slightly retracted; pupils dilated, but react sluggishly to light, the pupils contracting to light momentarily, with subsequent dilatation; cervical rigidity marked; respiration greatly increased; abdomen retracted; Kernig's sign well marked; patient semi-conscious and restless; temperature 103°. A spinal puncture was made and two ounces of clear fluid withdrawn, which showed the presence of *Diplococcus meningitidis intracellularis.*

Following the lumbar puncture, the child improved mentally, but was very restless; pulse was irregular in force and rhythm and of small volume. Two days after admission the patient received his first antitoxin injection of 6,000 units (January 23). After twenty-four hours, consciousness returned. On January 24 the child was much brighter; pupils react to light, contract, and then dilate; Kernig's sign well marked. Slight rigidity of post-cervical muscles.

The child continued to improve with practically a normal temperature, pulse, and respiration, but as a precaution, I administered another similar dose of antitoxin on January 29, following which the child improved to uninterrupted recovery, and was discharged free from motor and sensory symptoms on February 17.

CASE II.—L. P., aged 15 years, admitted on January 25, 1905. Two days prior to her admission patient complained of headache malaise, and anorexia. On admission patient was delirious, with marked hyperesthesia, marked photophobia; pupils contracted, moderate cervical rigidity. Kernig's sign well marked. Temperature on admission, 102°. A spinal puncture was made and three drachms of opaque fluid obtained, which showed the presence of the diplococcus intracellularis. Seven days after admission her temperature was 106°. She received an antitoxin injection of 8,000 units. This was followed by a general improvement in her condition, so that on the following day (January 26) the patient was quieter and practically conscious. Her condition continued to improve, and on January 31 she received a second injection of antitoxin of 8,000 units. This was followed by a complete cessation of all symptoms. Her convalescence was uninterrupted, and she was discharged from the hospital entirely well on February 16, 1905.

The following three cases—brothers—were admitted to the hospital at the same time. A fourth brother, who was taken ill with cerebrospinal meningitis, at about the same time they had become ill, had died at home, after an illness of less than 48 hours.

CASE III.—I. C., aged 10 years, admitted on January 30. Fulminating history. Two days before admission the child had severe headaches, pain in the neck, vomiting, etc. On admission the child was conscious, pupils equal and dilated, contract sluggishly to light; photophobia; marked cervical rigidity, slight retraction of the neck, Kernig's sign. A spinal puncture was made and eight drachms of turbid fluid which was under slight pressure was removed; this showed the presence of diplococcus intracellularis. Diphtheria antitoxin (8,000 units) was injected. A second antitoxin injection was made on the following day; again after three days; again after three days; again after two days; again after two days. In all, six hypodermic injections of diphtheria antitoxin of 8,000 units each were given in this case, and the patient went on to an uninterrupted recovery, being discharged from the hospital on February 20, 1905.

CASE IV.—P. C., aged 11 years, admitted on January 30. History before admission as in preceding case. On admission, stupid; pupils slightly dilated, react sluggishly, moderate photophobia; slight cervical retraction, well marked cervical rigidity; conjunctivæ injected; abdomen slightly retracted, Kernig's sign well marked, pulse irregular and barely perceptible; temperature 104°. Spinal puncture was made and four drachms of clear fluid obtained, which failed to show the presence of the diplococcus. On the following day, an antitoxin injection was given of 8,000 units. On February 1, two days after admission, the boy became brighter; pupils responded better to light; headache cleared up. An antitoxin injection of 8,000 units was given on February 2. This was repeated on the 3rd and 6th, after which the patient went on to uninterrupted recovery, being discharged from the hospital on February 20.

CASE V.—L. C., aged 7 years. Twelve hours before admission the child had chill, slight headache, and malaise. On admission there was slight retraction of the head, with marked cervical rigidity; pupils dilated, contract sluggishly, subsequently dilating, photophobia; abdomen retracted; well marked characteristic eruption; Kernig's sign well marked. A spinal puncture was made; eleven drachms of slightly turbid fluid was withdrawn. This failed to show the specific bacillus. On the following day an antitoxin injection was given of 8,000 units. This was followed by but slight improvement and was repeated at intervals of 48 hours on ten different occasions.

On February 21 (the 23rd day in hospital) an antitoxin injection was given and the following note made: "The child's general condition improved; almost conscious; pulse of better volume; fairly quiet; temperature normal; no motor or sensory symptoms present." This child gives every promise of recovery as complete as his brothers, except that convalescence may be more protracted, but the result apparently is positive.

February 28.—Pulse, temperature, and respirations normal; all symptoms have disappeared, the patient is practically well and only remains in hospital to convalesce.

CASE VI.—H. W., aged 14 years, admitted on February 8. Twenty-four hours before admission complained of headache, thirst, stiff neck. On admission the patient was in profound stupor; pupils moderately dilated but sluggish; no rigidity of the neck, but pain on pressure over the ligamentum

nuchæ. Temperature 105°. A lumbar puncture was made, but no fluid was obtained. Pressure symptoms being so urgent, a second lumbar puncture was made on the following day. The fluid withdrawn showed the presence of the diplococcus intracellularis. No antitoxin being available, the patient did not receive his injection until February 14. This was followed by an injection on the 15th, 17th, 20th, 21st, 23rd, and 24th. A gradual improvement took place in the mental and physical condition of the patient, although his temperature has not been markedly affected by the treatment.

February 28.—A general improvement has taken place in all symptoms, except there remains a persistent high temperature. Prognosis is still uncertain.

Case VII.—S. F., aged 19, a well-developed young woman. Ill three days prior to admission with headache, vomiting, restlessness, delirium, tenderness over the nucha. Condition progressing into coma. On admission patient was in profound coma, collapsed, pulseless, extremely cyanosed, pupils dilated, did not respond to light, abdomen retracted, Kernig's sign fairly well marked. This patient presented such profound evidence of toxemia that it seemed as though she would die before she reached the ward. A spinal puncture was made and 4 drachms of moderately turbid fluid withdrawn. This showed the presence of the diplococcus intracellularis. The spinal puncture was followed by moderate relief of symptoms, and an antitoxin injection of 10,000 units was given. This patient remained in an exceedingly serious condition for 72 hours, when a second antitoxin injection was given of 10,000 units. This was followed by an improvement in her mental condition; the pulse was of better volume, the rigidity of her neck was less marked, and a general though slight amelioration was noted in all her symptoms. This patient received antitoxin injections (10,000 units) on February 14, 15, 17, 18, 20 and 22. On the 17th, seven days after her admission, symptoms of pressure became so urgent that a lumbar puncture was made, but only 12 minims of fluid were obtained. This, however, gave some relief.

February 28.—Conscious; all symptoms have disappeared, but a slight rigidity of the neck; prognosis fairly good; recovery is looked for in this case.

Case VIII.—I. S., aged 3 years, admitted February 16. About 36 hours before admission the child was seized with vomiting. Cried out as though in severe pain. Extremely restless. On admission patient cyanosed; unconscious; there is slight retraction of the head, with well-marked cervical rigidity, pain on pressure over nucha; marked hyperesthesia; abdomen retracted; Kernig's sign marked; feet and hands cyanotic and cold. Lumlar puncture yielded 12 drachms of turbid fluid, which was positive for the diplococcus meningitidis. Diphtheria antitoxin (8,000 units) administered the same day. On February 17, the child's condition was practically unchanged; on the morning of the 18th, the child was conscious; general condition much improved, marked diminution in the irritability and restlessness; took nourishment freely.

February 21.—Antitoxin (4,000 units) administered. The child's mental condition was slightly worse; cervical retraction had become extreme. Antitoxin (4,000 units) administered on the 23rd and 24th.

February 28.—Conscious; lumbar puncture gives a fluid negative for diplococcus intracellularis. Child playful, all symptoms absent, but high temperature.

In this case, as in a number of others, I have remarked during the past 4 or 5 days an afternoon rise to 103° or 104°, followed by a morning remission to normal temperature. As this has only taken place in the last few days, and is a characteristic "pus temperature," I am inclined to think it may be due to abscess following the injection of antitoxin, although the strictest asepsis was observed in all procedures.

Case IX.—R. G., aged 12 years, admitted February 18. Twenty-four hours before admission, vomiting, there was pain in the back of neck, with headache. On admission the patient was wildly delirious; she kept up an incessant screaming for 36 hours (although she was given within 24 hours two-thirds of a grain of morphine, together with 20 grains of chloral, and 40 grains sodium bromide). Pupils contracted, nonresponsive to light; photophobia; rigidity and tenderness of the back of the neck; Kernig's sign well marked; abdomen moderately retracted; no rash. Lumbar puncture; 9 drachms of turbid fluid was withdrawn, which showed the diplococcus intracellularis; the fluid was neutral in reaction. Antitoxin (8,000 units) was administered on the 18th, 20th, and 21st, A speedy recovery of consciousness resulted, with a fall of temperature and a gradual improvement of all symptoms.

February 28.—Conscious, less rigidity at the back of the neck. Kernig's sign less marked, all symptoms improved. "Pus temperature." Prognosis very good.

Case X.—H. S., aged 22, admitted February 15. This case is exceptional in this series, inasmuch as the onset was very insidious. Five days before admission, patient complained of headache, chill, and vomiting. These symptoms subsided, except the headache, for the relief of which he came to the hospital. On admission, pupils equal and responsive; facial expression dull, a suspicion of rigidity about the back of the neck; Kernig's sign only suggestive. On both shoulders a few irregular, but not characteristic hemorrhagic spots were noted. The following day, the apathy increased and the pupils were more sluggish to light. The Kernig's sign, while not positive, was more pronounced than the day before. In the absence of any organic lesion, a lumbar puncture was made, and 9 drachms of slightly turbid fluid withdrawn, which showed the presence of the diplococcus intracellularis. Antitoxin (8,000 units) was given on February 18. On the 20th, 21st, and 23rd, 10,000 units were administered; these latter doses were followed by a most profuse general rash, erythematous in character, which disappeared after 48 hours. The patient showed a marked improvement in all the symptoms noted.

February 24.—The patient again became dull and apathetic, pulse very slow, 58 to 60 per minute, pupils contracted. These symptoms all increased in severity, during the next 24 hours, and the patient died in profound coma on the following day, 10 days after admission to hospital. Autopsy refused.

Case XI.—A. W., aged 7, admitted February 18. The patient is a younger brother of Case VI, who has been in the hospital two weeks suffering from epidemic cerebrospinal meningitis. This patient gives a history of 24 hours of headache, vomiting, and malaise. On admission patient is conscious, has slight retraction of the head, moderate cervical rigidity, pupils dilated, contract momentarily to light, then dilate; abdomen retracted, Kernig's sign present, no rash. Lumbar puncture was made, and 4 drachms of turbid fluid was withdrawn, which showed the presence of diplococcus intracellularis. This case was mild from the onset.

Antitoxin (8,000 units) was given on February

18, 20, 21. February 23, bed-side note: all symptoms have improved.

February 28.—This patient continued to improve, and was discharged from the hospital on this date, entirely well.

Case XII.—Y. C., aged 19, admitted February 17. Four days before admission, patient had headache, projectile vomiting, partial loss of consciousness, and pain at the back of the neck. These symptoms steadily increased. On admission, was extremely cyanotic, apparently moribund; profoundly unconscious, pulseless; pupils wildly dilated, no reaction to light; cervical rigidity marked, slight retraction of the head; abdomen retracted; Kernig's sign present; hemorrhagic eruption. On lumbar puncture, 4 drachms of a slightly turbid fluid were withdrawn, showing the presence of diplococcus intracellularis.

Antitoxin (10,000 units) was administered at once, and repeated on the 18th and the 20th. This patient showed great improvement as the result of the lumbar puncture and the cardiac stimulants administered. Following the antitoxin injection consciousness returned, and while the general picture was unfavorable, a decided improvement was shown after two days of treatment. This improvement continued for four days. On the night of February 20, she was seen by Dr. Colton at 12:30. At that time she was in about the same condition as she had been for the preceding 24 hours. At 3 P.M. she took some milk and had slight difficulty in swallowing, after which she apparently fell asleep. At 4:30 A.M., the nurse, in making her rounds, found the patient had died. Autopsy was refused.

Case XIII.—M. F., aged 4, admitted January 17. This patient presented the clinical picture of epidemic cerebrospinal meningitis, and, although lumbar punctures were made on January 17 and 18, with negative results, this diagnosis was made. On January 22 a lumbar puncture was made, and one drachm of very turbid fluid withdrawn, which showed the diplococcus intracellularis. Although antitoxin injections of 8,000 units were made on January 23, 30, February 3, 6, 8, 10, 12, 14, 15, 17, 21, the patient showed no response to this mode of treatment. It may be of interest to note in this case that pus from an abscess showed the presence of the meningococcus.

On February 28, the following note was made: "During the past week condition unchanged; patient apparently dying from asthenia.

Case XIV.—J. V., aged 9, admitted February 18. This patient arrived in New York City from Pittsburg, February 13. The following day she had headache, vomiting, and severe diarrhea; after a short time this was followed by bloody stools. On admission, conscious, pupils equal and dilated, react to light, but dilate after contraction; no cervical retraction or rigidity, but pain on pressure over nucha; Kernig's sign only suggestive.

A lumbar puncture was made, and 7 drachms clear fluid withdrawn, which failed to show the presence of the diplococcus intracellularis. Antitoxin injection of 8,000 units was given on February 20, 21, 23, 24, and 25.

February 28.—General condition good, all symptoms absent, except high temperature (pus). Prognosis good; recovery fairly certain.

Case XV.—B. H., aged 9, was seen in consultation with Dr. J. B. Kopf at Bay Ridge, on February 17. History of four days of delirium, vomiting, high temperature, pain and rigidity in back of neck. At the time of my visit he was slightly delirious, rigidity of neck marked, abdomen retracted, pupils slightly dilated and nonresponsive to light, Kernig's sign well marked; no rash. Lumbar puncture was made, and ten or twelve drops of turbid fluid withdrawn. Diphtheria antitoxin (6,000 units) was injected; this was followed by a sharp rise of temperature and convulsions; injection repeated on the 19th, and 9,000 units were given daily until the 24th, when Dr. Kopf wrote to me that the patient was conscious, neck only slightly rigid, temperature normal, "the clinical picture is much less serious and he seems to me to be getting well." The antitoxin was discontinued because of the occurrence of a profuse rash.

Case XVI.—G. E., aged 9, admitted February 24, with a history of four days of headache, vomiting, semi-coma, and pain at the back of the neck. On admission, pupils dilated, nonresponsive to light, opisthotonos slightly marked, neck very rigid, Kernig's sign well marked, slightly delirious. On lumbar puncture, 6 drachms of turbid fluid withdrawn, showing presence of diplococcus intracellularis. Antitoxin injections (8,000 units) on February 24, 25, and 27. The day following admission, patient was conscious, general picture more satisfactory.

February 28.—Patient conscious, neck less rigid, pupils respond to light. This patient has been under observation so short a time as to make a prognosis practically impossible, although her condition to-day is much more satisfactory than it was at the time of her admission to the hospital.

Case XVII.—L. K., aged 4, admitted February 26, with a history of two days' illness; vomiting, headache, macular rash, rapidly disappearing. One brother died of this disease after one day's illness, another brother died a few hours after being admitted to the hospital. On admission, rigidity of back of the neck, but no pain on pressure over nucha; patient is dull and apathetic; Kernig's sign is absent. On lumbar puncture, one drachm of purulent fluid was withdrawn, which shows the presence of diplococcus intracellularis.

Antitoxin was administered (7,000 units) on the 26th and 27th.

February 28.—On account of increased cerebrospinal pressure symptoms, a second lumbar puncture was made last night, and 6 drachms of semi-purulent fluid was withdrawn. After a few hours, profound coma developed, and the child died. Duration of illness, three days.

I have detailed in brief the history of 17 cases. Of these, 5 patients recovered completely; 3 died, and 9 are still under observation. Of the latter, 5 give every promise of a speedy recovery; the other 4 are still in a serious condition, and I would not venture to make a prognosis.

The case to which I should like to call special attention is No. 13. This little girl was in the hospital 7 days before I began the administration of diphtheria antitoxin in this disease. Her history has been detailed, and it seems reasonable to suppose that her present condition, that of mental and physical torpor (the condition which was so frequently noted in cases before this series, and which is but the result of the action of the specific poison on the brain producing encephalitis), might have been warded off had the antitoxin been administered before the lapse of nine days from the beginning of her illness.

While the number of cases reported is small, the time of my observation was also limited, my term of duty at the hospital ending on March 1. The greater number of cases were severe in their onset, and the evidence of profound constitutional infection well marked. In five cases, I am satisfied that nothing but the lumbar puncture and cardiac stimulation

(the former being in my judgment of most value), together with the early administration of antitoxin, would have maintained the life of the patient for half a day.

It was in just this kind of cases we observed the best results; within two days delirium or coma abated or disappeared; the pulse and temperature became more nearly normal, the tongue more moist, and, in a word, a general improvement in all the symptoms was manifested. In no case was consciousness absent after three days. The dose given was 6,000 units to children less than 5 years of age; 8,000 units to those between 5 and 12, and 10,000 units to adults. This amount was injected under the scapula on alternate days. During the past week it has been given daily in severe cases, and in improving cases in smaller doses at less frequent intervals. In a few cases an antitoxin rash developed, but never was of much moment. The greater number of injections were followed by a fall of temperature, but occasionally a rise of from two to four degrees was noted. In all cases having albuminuria, the albumin was also found on admission, and therefore could not be charged to the antitoxin, but was probably dependent on the high temperature or toxemia. In fact, not a single bad symptom developed as the result of the administration of the antitoxin.

A peculiar feature of this series of cases was the absence of marked opisthotonos. Although cervical rigidity and pain on pressure over the ligamentum nuchæ was present in every patient, only two of them showed the marked retraction which is always mentioned as a characteristic symptom of the disease.

From the study of these cases, I am of the opinion that the temperature indication is of less consequence than any of the other prominent symptoms, and that its permanent fall takes place after the other symptoms have shown abatement. In making an estimate of the progress of the disease, I have relied most on the mental condition, as it seemed that more normal mental activity takes place before the abatement of the temperature and high pulse rate.

This series of observations was made, not at the termination of an epidemic, when one would naturally expect a series of mild cases with fairly frequent recovery, but at the recrudescence of an epidemic, when the symptoms are fulminating and the mortality high. Of course, many cases of this disease have been reported in which so rapid a recession of symptoms have occurred as to make one think they belonged to the so-called class of aborted cases. This, however, is unusual in the early history of an epidemic, and never in so large a proportion as in this series.

I shall not attempt to enter into a discussion as to the action of the antitoxin in this disease, leaving this part of the subject to Dr. Wolff, who informs me he is about to present his views in the matter to the profession.

As to the mode of administration: From a study of these cases, I am led to believe that a larger dose of antitoxin is necessary than is usually given in diphtheria, and that it should be repeated daily until urgent symptoms abate (not to the exclusion of lumbar puncture, which should be made for symptoms indicating cerebrospinal pressure). With the subsidence of delirium or coma, a lessening of the rigidity of the neck, of headache and photophobia, it is advisable that the amount of antitoxin be diminished, but its use should be continued at longer intervals until all central nervous symptoms have subsided.

My observations have been entirely clinical, and I think have been sufficiently encouraging to warrant a continuance of the treatment. There can be no doubt but that a diminution of mortality has taken place, and so far as has been observed, an absence of sequelæ.

In this connection it may be interesting to note the frequent coincidence of an outbreak of epizootic in horses (pink-eye), with the epidemic of spotted fever; and to the fact that the microorganism in both conditions is the same, diplococcus intracellularis. An investigation into this matter would be interesting.

To summarize: During the past five weeks there have been seventeen cases under observation, of which 5 have recovered completely; 3 have died, of whom 2 were adults; 9 cases are still under treatment. Of these, 5 show such marked improvement as to indicate probable recovery (4 being convalescent). Of the remaining 4 cases, all are in a serious condition, and prognosis is impossible at the present time.

One case (No. 13), in which antitoxin treatment was commenced on the 9th day of the disease, will probably die from asthenia.

Should the result of these cases be but an earnest of the future treatment of this disease, I believe to Dr. Wolff belongs the credit of having discovered the remedy for one of the most fatal diseases, and of having placed at our disposal a plan of treatment not second in its results to the antitoxin treatment of diphtheria, the mortality of which, by its use, has been lessened about two-thirds.

I wish to make acknowledgment to Dr. Edwin A. Colton, house-physician at Gouverneur Hospital, of my thanks for his earnest and painstaking efforts in behalf of this plan of treatment and for the clinical histories here reported.

209 West Seventy-Second Street.

CHRONIC MYOSITIS RHEUMATICA AND ITS TREATMENT BY MASSAGE.

By GUSTAF NORSTROM, M.D. (Stockholm),
NEW YORK.

Chronic myositis rheumatica may follow acute myositis, or, what is more common, it is chronic from the start.* It was studied only very imperfectly until the fact was recognized that its clinical domain was more widespread than had been supposed and that massage was the sole remedy of value. The affection was considered for a long time from but one clinical standpoint, namely, as secondary to rheumatism, having the same general pathological and symptomatic relationship, and that it consequently would be useless to treat it separately. Froriep[1] was the first to point out the independent existence of chronic myositis, or rather the most constant of its external manifestations; yet he did not believe that the indurations discovered in certain persons, which he called rheumatic (rheumatische Schwielen), were of an inflammatory nature. The lesions did not, according to him, always have their seat in the muscular system. Froriep several times also found deposits of induration in the skin, in the subcutaneous cellular tissue, and even in the periosteum.

In spite of this the opinions of clinicians were not settled. In 1867 Oppolzer,[2] taking up Froriep's ideas, again concluded, after having examined a hardened mass of the soleus muscle, that it was purely a rheumatic lesion, having nothing inflammatory about it. He added that indurated areas of this sort were very commonly found in the muscles.

*The reason why traumatic myositis is incidentally spoken of is because it presents many points of similarity with that type which forms the subject of this article.

It has been proven that chronic rheumatism can produce deposits, which may have their seat in the connective tissue, under the skin, under the periosteum, or, most frequently, in the depths of the fleshy parts of the muscles. But most authors have regarded these only as a manifestation of a general process in which the whole organism is concerned, a sign of incontestable symptomatic value, which in most cases disappears spontaneously under the treatment of rheumatism proper. A second school has treated the subject from quite a different standpoint. This regards acute and chronic myositis as the fundamental affections and holds that the original diathetic tendency must be modified only in order to prevent the recurrence of the local affection. These last conditions must be treated first. Metzger's experience soon led him to analyze these phenomena more minutely than had been done before, and we can say without exaggeration that he, in advocating this theory and at the same time formulating an appropriate treatment for the affection, is to be regarded as the real father of the doctrine of muscular inflammations. The article which my countryman, Helleday,[3] published many years ago on this subject was the first one in which chronic myositis was regarded from this point of view. This was soon followed by articles of less importance, by Mosengeil,[4] Gies,[5] and others.

Myositis Chronica Rheumatica.—The only form of chronic muscular inflammation that interests us here may pathologically be designated as myositis interstitialis. Perusing the literature of the subject one finds that a great deal has been written regarding the pathological anatomy of myositis, but on sifting the material, it is not difficult to distinguish that what is said refers to other forms of myositis than the one we have in view. Only Strauss[6] makes an exception to this rule. He treats, not very extensively, of the affection which is the subject of this article, although exclusively of the advanced or indurated form. This is made clear by the designation he gives to his article "*rheumatische Muskelschwiele.*"

As Dr. Adler[7] of this city states in his excellent article on muscular rheumatism, in which he says a great deal about chronic myositis, it is hard to obtain proper anatomical material for adequate histological research. People do not die of muscular rheumatism or chronic myositis. "However, thanks to occasional excisions of diseased muscles in the living subject, and to opportune and lucky finds in the corpse, enough material has from time to time been available to enable us to arrive at some idea of the actual pathological conditions on which these muscular lesions are based." I give his statement *in extenso,* as it is the only one available for our purpose. "In one or more places of the muscular system hyperemia with dilatation of the smaller vessels and capillaries, sometimes even accompanied by small hemorrhages, takes place. This is at once followed by a more or less copious emigration of cells into the interstitial tissues, the leucocytes crowding between the bundles of fibers and even between the single fibrils. Very soon active proliferation of the interstitial connective tissue takes place, and thus in a comparatively very short time after the beginning of this process an infiltration of the muscle is brought about, which varies in extent and density according to the intensity of the process. During all this time the muscle fibers themselves are not very materially affected; they are pushed apart to some extent, but do not greatly suffer. In the milder type of cases the process ends here. In due time, usually after but a very few days, absorption of the infiltrating material takes place. The muscle returns to a condition practically, though perhaps never quite, normal. If, however, the inflammatory activity attains a higher grade of intensity, the process does not end with the mere cellular infiltration, and at most a very slight degree of connective-tissue proliferation. More extensive new formation of fibrous tissue is inaugurated, sometimes to quite a considerable degree. The interstitial connective tissue proliferates vigorously; the muscle bundles and fibrils have been forced apart and compressed. They also begin to degenerate and are destroyed, exactly in the manner described for interstitial myocarditis. The result of this is a fibrous induration of the muscle. It is evident that when this stage of fibrous induration has been reached, spontaneous restitutio ad integrum is no longer possible.* If left to itself, the induration will remain, impeding function, causing pain, and facilitating the recurrence of other acute attacks, thus leading over from acute to chronic muscular rheumatism." This seems even to show that chronic myositis is merely a more or less advanced stage of chronic rheumatism.

The insertions of the muscles in reality constitute the most favorable seat for this affection. It is here that it is most frequently met with, for example, in the nape of the neck, in the extensors of the forearm near their upper insertion, etc., but it would be erroneous to suppose that isolated deposits do not exist in the fleshy parts and at a distance from the muscular insertions. Chronic myositis may be found in all parts of the body, in the head, the neck, or the trunk and all the limbs. Most of the deposits, if not all, are, as I have already mentioned, spontaneously produced in people suffering from rheumatism. Usually there is a history of preceding or simultaneous rheumatic affections in other parts of the body. Treatment by massage has had the advantage in calling our attention to the real nature of the symptom complex which nobody before had thought of connecting with the muscles. The symptoms had been referred to the digestive apparatus, the nervous system and the general state of health, such as, malnutrition of the body, but no one ever supposed that an apparently mild lesion and one which was neither painful nor extensive, could be the cause of such disturbances as muscular inflammations are able to produce.

It often requires a great deal of practice in manipulating healthy muscles, to be able to distinguish them from abnormal ones, and to this end one must acquire what Metzger calls "das normale Fleischgefühl." One will then feel that in cases of recent myositis palpation gives a sensation of decreased elasticity, of a more doughy consistency. And as the muscle increases in consistency and becomes gradually harder, the difficulty in diagnosticating decreases, to become very slight, when the deposit, probably through the above mentioned increase in the interstitial tissue, has arrived at the hard consistency of an induration.

I divide chronic muscular inflammation into three stages: (1) A *swelling,* manifesting itself only in the shape of a puffiness of the muscles. (2) *Resistance,* when the inflamed area is to some degree organized and resistant to the touch, although still preserving a certain degree of elasticity. (3) *Induration,* when the consistency is very hard, sometimes as hard as cartilage, no elasticity whatsoever being left.

The transitions of the different stages are not

* This is even the case in an earlier phase of the disease which we call the stage of resistance. (Remark of the author.)

clearly marked. At times, two stages, even three, can exist simultaneously in the same inflamed area. It is self-evident that if there are several inflammatory spots present at the same time, all of them need not necessarily represent the same stage of the disease. On the contrary, we frequently see them representing different stages, from the single swelling to a very hard lump, distinctly separated from the surrounding healthy tissue or gradually merging into it. The essentially chronic muscular inflammatory process is, as a rule, not recognized at its origin, as it develops mostly from a preceding rheumatic condition, the pain to which this gives rise being easily confounded with that resulting from chronic myositis. Taking into consideration the slow development of chronic myositis, everything tends to the belief that a longer or shorter length of time has elapsed before it is possible to recognize it, but we have no means of determining the duration of this period. Furthermore, the muscular inflammations develop in different ways, in some cases slower, in others more quickly, but the same inflammatory stage, in some individuals, produces symptoms early and in others late. As an example of the above statement that muscular deposits mostly develop insidiously, that is to say, in a latent way and without giving rise to any noteworthy pain or to any other symptoms, until lameness or more or less pronounced stiffness has set in, and the attention of the patient is directed to his condition. I quote the following case.

Last February, a gentleman, 65 years old, was sent to me by Dr. Theobald of this city, to be treated for muscular inflammation seated in the region of the hips. Several diagnoses had been made, but none of the examining physicians, save the last one, had recognized the condition as chronic myositis. The patient did not complain of anything worth speaking of, but for about eight months he had suffered from a stiffness in the hip region, which had gradually been increasing, and finally developed to such a point that at this time he was walking only with difficulty and pain, getting fatigued very easily. He felt so stiff that after having been seated for a little while, it was only with great difficulty he was able to stand up and walk. This was particularly the case in the morning for a short time after he had left his bed. I found the whole of the gluteus medius on both sides transformed into a very hard mass of indurated tissue not susceptible to any compression on the part of the examining finger. Besides, there were deposits of different size, and of the same consistency in the gluteus maximus and minimus. On account of the extreme hardness of these lumps and their great size, as well as of the age of the patient, it was only after about three months that I was able to rid him of the deposits. He now walks as well as ever, and does not feel the slightest stiffness in his hips.

Chronic myositis is not, as it is generally believed, a rare disease, on the contrary, it is one of the most frequent affections of the human body, although very seldom diagnosed, and consequently very little known. The pain of chronic myositis does not have any particular character. Mostly it resembles, as I have already mentioned, that of chronic rheumatism, for which the disease we are speaking of is most frequently mistaken, and one can, I think, without committing an error, claim that, when the pain mentioned has a tendency to remain obstinately in one spot, and recurs again and again at the same place, one may be almost sure that one has not only to deal with an ordinary muscular rheumatism, but with real inflammatory condition of the muscle, a supposition almost always confirmed by a subsequent examination.*

I think there exists no affection in the human body which so often leads to error in diagnosis, as does chronic myositis, and this particularly because I have noticed that the disease is as little known in this country and in England, as it was in France when I first settled there. In Germany, also, it is far from being as well known, as it deserves to be. Even in modern works on pathology, as for instance in the voluminous and much read treatise on this subject by Eichorst,[8] there is almost nothing written about chronic myositis, and in the extensive work on diseases of the muscles (Die Muskelerkrankungen) by Prof. Heinrich Lorenz, in which one might hope to find a long chapter on myositis of rheumatic origin, no doubt the most frequent of all and at the same time the only one which can have any practical interest, there is only slight reference to this variety, while there is a great deal on different kinds of myositis of other origins, much more rare, as traumatic, infectious, tuberculous, syphilitic myositis, not to speak of myositis ossificans.† In this country Dr. Isaac Adler is the only one, who, as far as I know, and only incidentally, has published anything on this subject.[9]

The affections with which deposits of myositis can be confounded are so many that I cannot mention them all here. They are often mistaken for infiltrations of the skin and subcutaneous tissues; swollen glands, particularly in the neck, are sometimes confounded with myositic deposits.‡ Myositis in the chest-muscles is frequently taken for pleurisy, and particularly for intercostal neuralgia. Besides, I have from time to time seen how myositis can be mistaken for an intraabdominal affection, as for instance perityphlitis. In the following case, this quite an acute one, myositis in the psoasiliacus muscle, was confounded with lameness of the lower extremities supposed to result from concussion of the spine. Only some weeks before I left Paris for New York, I was called to see an elderly gentleman, who, while riding in the Champs Élysées, was thrown from his horse. In order to avoid falling forward, he suddenly threw his body back. Immediately afterwards, he felt a sharp pain in both sides of the abdomen, and it was impossible for him to take a single step. He was carried home, where several physicians saw him and declared that he suffered from a concussion of the spine. I saw the patient four days after the accident had taken place. During this time several treatments had already been tried without any effect. Absolute impossibility to lift the legs from the horizontal plane existed. No spontaneous local pain. Slight fever. On examing the hypogastrium and pressing deeply, the patient complained of a violent pain on both sides, but particularly on the left one. I made the diagnosis of

* As rheumatism is almost always the causative factor of myositis, it is easily understood why so many persons, suffering from this affection, feel relieved, at least for a time, by having recourse to antirheumatic treatment, and particularly to thermal baths. It may be that after a visit to one of these baths, the patient feels more or less free from pain for weeks or even months. He does not fail to return the following season to the spring which has procured him even transitory relief; and so it goes on from year to year until the real cause of the trouble may be discovered and removed. And all this is of daily occurrence.

† I regret very much not to find anything more regarding the disease under consideration in the second volume of this work, published last spring, than was in the first volume.

‡ It is easy to differentiate them, as the glands have a more globular form, while the deposits of myositic origin are more flat; the former roll under the finger, while the latter, forming a part of the muscle, only move with this.

acute myositis of the psoasiliacus muscle, caused by a violent effort to keep up the equilibrium of the body, with subsequent partial rupture of its fibers. I treated him by massage (twice a day), rendered easy by the thinness of the integuments. After six days the patient was able slightly to raise the legs from the bed, and after fourteen days of massage he could walk without any inconvenience, and without having the slightest pain.

A diagnosis of chronic neuritis is often made when in reality the pains are due to chronic myositis, a mistake in diagnosis which I have observed on numerous occasions. More frequently in France than in this country. I have seen the pain in the sacro-lumbar region, resulting from a chronic myositis diagnosed as a symptom of neurasthenia (sacralgia of Charcot), if the patient at the time presented other symptoms referable to the nervous system. Another error in diagnosis is frequently made in cases in which the patients complain of a more or less constant pain in the lumbar region. The physician consulted often diagnoses the pain as dependent upon some disease of the kidney, treatment of which, however, brings no relief. A case illustrating this, and showing the serious consequence an error of diagnosis might lead to, had not the right condition been recognized in time, is given herewith.

Mrs. L. Six years ago I saw a lady of middle age, who had come to New York from one of the neighboring States for the purpose of being operated upon for a supposed calculus of the kidney, as diagnosed by several physicians at home. But before undergoing the operation already decided upon, she was persuaded by some friend of hers to consult Dr. Adler in this city, who, upon examination, came to the conclusion that the pains were due to chronic myositis, and not to calculus. The deposits were situated in the small of the back, and gave rise to a persistent and most annoying pain, from which the patient had been suffering for several years. Dr. Adler having had the kindness to recommend the patient to my care, I found on examination in the left sacro-lumbar muscle two large nodules, also two others at the same level on the right side. The first mentioned had reached the size of a fifty-cent piece, and were distinctly indurated, besides being very painful to pressure. As I had to leave New York in a month for my summer vacation in Europe, I was obliged to institute two seances a day from the beginning of the treatment, and to apply most energetic massage to the muscular indurations. After a month's treatment, they had all completely disappeared, and about a year later I heard that the patient had had no return of her pains.

What I have observed in the cases above mentioned, applies also to affections of the uterus and its adrexa. Not a few curettages have I seen performed without any benefit, and several other methods of treatment resorted to in supposed uterine affections, until examination revealed one or several myositic deposits in the sacrolumbar region as the real cause of the lumbar pain. Pressure on the muscles in the lumbar region would promptly clear up the diagnosis; for, if the pain is due to myositis, pressure will intensify it, while, if due to the uterus, pressure neither produces nor intensifies it, as in this last case the pain is only a radiated one.

Sometimes myositis in the lower extremities is mistaken for the so-called growing pains in children and young people. I do not deny that what is commonly called growing pain really exists, but I believe that a great many of these affections are due to other causes and particularly to chronic myositis of the muscles of the legs. It is easily understood why I have not more often seen cases of this kind, as naturally nobody would imagine that a chronic myositis could be accountable for a permanent pain in the legs of children. But I have come to this conclusion from what I have seen during my sojourn in Paris, where I successfully treated several cases of this kind. Two years ago I had the pleasure of being able, in this city also, to rid a girl, ten years old, from this affection, which is often more annoying than really painful. Last spring I was consulted for the same trouble in a girl six years old, in a family where I was at the time treating mother and father for muscular inflammation in various localities. I discovered several nodules of moderate hardness in the little patient's legs below the knee. Different diagnoses had been made but particularly the above-mentioned one of "growing pains." After six weeks of massage very little remained of the swellings mentioned, and the pain was almost gone, allowing the child to sleep perfectly well, and to run about without feeling any fatigue. As the family was going to Europe, the treatment was interrupted. It is not infrequent either that the edema, sometimes quite considerable, due to muscular induration seated in the lower part of the leg, is mistaken for Bright's disease, if there are at the same time some, even small, quantities of albumen in the urine. I have seen several cases of the kind in Europe, as well as in this country, but I recall particularly one patient, a Russian general of advanced age, whom I saw in Ragatz in the summer of 1893. I found him scarcely able to move about, and with his limbs swollen to an enormous degree up to the knee. He told me he had called me in in order to ask me if I could help to rid him, even only temporarily, from the most annoying swelling, and enable him to walk. I examined him locally, and found two big, rather hard, masses in one leg and two in the other, situated slightly above the ankles; moreover, another one, this one smaller but just as hard as the others in the fleshy part of the calves. Examination of the urine showed the presence of a small quantity of albumen; but this I believed I could place to the account of a gastrointestinal trouble, from which he had been suffering for some time. I promised him a complete and radical cure, which he, of course, had not hoped for, so many eminent physicians having diagnosed his case as one of Bright's disease. After six weeks of massage (two seances a day), the patient was entirely free from edema, and at the same time the deposits of myositis had quite disappeared. During the fortnight the patient continued to stay in Ragatz, even when he had been all day on his feet, there was not the slightest tendency to a return of the swelling. The following year I saw him again in Ragatz, where he had come to be treated by me for his stomach and bowels (constipation). He recovered completely from these also, and the following spring he wrote me, telling me that the albumin in the urine had been entirely absent for some months. The swelling of his legs had not reappeared, and he was enjoying the best of health.

Sometimes, as I have seen it happen, the association of functional heart murmurs with swelling in the region of the ankles, may lead the examining physician astray. A muscular inflammation in the lower extremities may account for the whole trouble. Lastly, a disease with which myositis is very frequently confounded, is an affection not known outside of Sweden, where it goes under the name of *panniculitis*.* This is a more or less circumscribed inflammation of the adipose tissue or rather of its

* Fortunately an error of diagnosis cannot here lead to any bad consequences.

interstitial connective fibers. There is, however, this difference between the two affections, that the latter admits of displacement on the subjacent muscular layer and that, contrary to what takes place in myositis deposits, it is movable to a certain degree, if you seize the inflamed mass between the thumb and forefinger. Besides, it is probably owing to the skin being richer in nerves than the muscles, that this is more sensitive on pressure than a myositis deposit. Sometimes the panniculitis is met with at the same time as deposits of myositis, which speaks in favor of a common predisposing cause (rheumatism); in some cases they are combined in such a way that the former covers the latter, which is then discovered for the first time after the panniculitis has been, through massage, more or less reduced in size.* Even cholecystitis can be mistaken for myositis, strange as it may seem. During my stay in Paris I saw such a thing twice, in one case the operation had already been decided upon; since coming here I have seen it in one case. Besides, Dr. Adler reports in his above-mentioned article, an observation of the same kind, and I hear from him that he has lately met with another similar case. Later, in speaking of myositis in different parts of the body, I shall allude to some other very interesting errors, which have been, and which are easily made, if proper precaution is not exercised. Lack of space does not permit me to mention all the different locations where a chronic myositis has been the cause of a wrong diagnosis. But the errors of diagnosis, which I have already noted, and those which I am going to state later, are, I think, the most frequent and are sufficient to direct the attention to the frequent existence of an affection which has, it seems to me, thus far received too little attention on the part of medical men.

We shall now review the phenomena of myositis observed in various regions.

Region of the Head and Neck.—Stiff neck (Torticollis) of muscular origin. Torticollis is a very common affection. It is observed in acute and chronic cases. When quite recent, it is easily overcome by massage. The results are less satisfactory if it is chronic, and particularly if it is inveterate. I am inclined to believe that congenital torticollis is of inflammatory origin. The cause of it is probably the rupture of a certain number of muscular fibers in the sternomastoid muscle during parturition or even during intrauterine life. The faulty position of the head is the consequence of the preceding inflammation. If treatment by massage could be employed at an early period of life, the affection might be easily cured by it; but as the patient is usually seen first at a later period during childhood or at adult age, only insignificant results are obtained by means of massage and rectification of the head. Recourse must be had to tenotomy. It is often claimed, I do not know why, that torticollis is exclusively produced in affections of the sternomastoid muscle. I have just as frequently, save in the just mentioned congenital form, seen it in chronic rheumatism or chronic myositis of the trapezius. Torticollis almost always depends upon an affection of this muscle, so that, after restoring its integrity through massage the deformity disappears. Some years before I left Paris for this country, Mr. E. from Cincinnati, came to see me, recommended to my care by Prof. Charcot of Paris. This gentleman had, more than a year before I saw him, been thrown from his horse, and had sustained a rupture of some muscular fibers on the right of the median line of the neck, apparently affecting several muscles, and particularly the trapezius. Hence there followed considerable swelling with pain and impossibility to move the neck. An immobilizing bandage was applied, and, when this was removed at the end of two months, the head had been turned to such a point to the right, that the chin almost touched the shoulder; it had become almost immobilized in that position and allowed only very little mobility in any direction. On examining I found, on the right side of the neck, a big mass almost as hard as cicatricial tissue, no doubt the final stage (induration), of a chronic myositis, which once was acute. Besides there was a very pronounced scoliosis with a curvature of the spine to the left, compensated by another lower down in the lumbar region, in the opposite direction; on account of this the patient presented a grotesque appearance in walking. Energetic massage of the swelling, accompanied by passive movements (rectification) of the head, overcame the vicious position. But it took more than two months before all deformity disappeared and the head had entirely recovered its mobility. I saw the patient's brother the following summer, who told me that during the fall following the treatment, the deformity of the body had also gradually yielded, and that his brother was then perfectly straight. To this case of traumatic origin I will add the following, resulting from chronic rheumatism in a patient suffering from various manifestations of the disease, among which chronic torticollis was perhaps the most prominent. Mr. W. S. has suffered for several years from pains of a distinctly rheumatic nature in different parts of the body. For about three years he had noticed a gradual increase in all of the symptoms, notwithstanding various treatments employed. Some months before I saw him, in the beginning of November, 1902, he had been under the care of a specialist in rheumatism of this city. The most energetic treatment employed by the latter had had no other results than to derange his stomach. At this time I found the patient in the most deplorable condition. He had grown very thin during the last year, and passed most of the nights with very little sleep. Although barely forty-five years old, he walked like a septuagenerian, stooping forward and complaining of an almost constant pain, and great stiffness in the lumbar region. Besides, there was a permanent dull pain with a feeling of weakness between the shoulder blades. His head was almost immobilized, permitting of only very little rotary movement. Passive movement was equally limited. The right arm could be lifted by the patient only half way up to the horizontal plane. Immobilizing the shoulder, in order to exclude any movement except that in the humeroscapular joint, and raising the arm one could only reach a plane lying several centimeters below the horizontal. Beyond this point there was only very little more extension of the arm possible, owing no doubt to the shrinkage and shortening of the capsule of the joint. In addition to this there was no part of the body where the patient had not more or less pain, which is easily explained by the fact that upon examination I found no less than sixteen different deposits of myositis, scattered over the body. Those situated in the right arm, back, and especially in the neck (involving nearly all the muscles in this region), were much indurated and of an almost cartilaginous consistency. Treatment by daily massage, together with forced movements of the humeroscapular joint was con-

* As I intend later on to publish an article on this affection, whose seat of predilection is the lower extremity of the trunk, I shall not at present go into particulars. I will only briefly allude to the fact that these inflammations of the adipose tissue are, like cases of myositis, curable by massage. In fact, massage seems to be the only means of exercising any influence upon the affection.

tinued with profit for several weeks until the patient had to go to Europe. Upon the advice of Dr. A. Robin of Paris, he passed a season at Dax, where he took the mud baths. After his return here, the following November, I found him much improved from his general rheumatic condition, especially in regard to the effusions in the smaller joints, synovial burs and sheaths of tendons, but the baths had not had the slightest influence upon the chronic myositis. Treatment by massage was again begun, and although continued very irregularly, led finally to a complete cure. By the end of March the patient could move his head and right arm in every direction, all the pains and disability had disappeared, and he could walk perfectly straight. When I saw him in the beginning of last November, he looked healthy, and said he had gained forty-two pounds, and felt perfectly well.

During my residence in this country, a period of about nine years, I have treated two similar cases of chronic torticollis in which there was almost total lack of motion. After treatment by massage for two and a half and three months respectively, a complete cure was effected in each case.

Pain resulting from myositis, which has its seat in the nape of the neck, and in the neck proper, sometimes radiates out into the muscles of the arm and forearm, and produces improper attitudes, depending less upon contractures, properly so called, than upon positions involuntarily assumed by the patient in order to relax the muscles, and thus to relieve the pain. More frequently the pain is expressed in nerves of the scalp, and not in the brachial plexus of the side involved. These phenomena belong to the cephalalgias of local or muscular origin. In making the apparently paradoxical assertion that headache is cured by massage, we mean to say that there are headaches resulting from chronic myositis of the muscles of the neck, and these make up the majority, contrary to the generally accepted opinion, which are perfectly curable by massage, while others due to a general cause, such as neurasthenia, hysteria, and chloroanemia, are of course not amenable to this treatment. Like most of those who have studied massage, I was led to study the muscular system more closely than is generally done, and I have come to the conclusion that it is often a limited myositis of the neck which is the cause of the cephalalgia, neuralgic or otherwise. These cases deserve a great deal of attention, and when treated by massage, will be promptly cured.*

I can speak with a great deal of confidence and positiveness on this subject, because I have often had the opportunity of treating such cases, and have in the majority of them, produced permanent cures. With the disappearance of the muscular inflammation all headache disappears. If you are confronted with a headache, so-called rheumatic, with a neuralgia of the head or the forehead, or with an ordinary migraine, whose origin is obscure, do not confine your examination only to the region which is the seat of the pain. I have discovered myositic deposits on the margins of and on a level with the cranial attachments (less often in the fleshy part) of the trapezius, splenius, sternomastoid, scaleni, and even in the temporal muscles. Some might claim that this is a coincidence, but it is by no means so. Pressure on these deposits was often sufficient to produce an attack similar to those previously experienced by the patient. When the suspected deposits were caused to disappear, the paroxysms ceased permanently in most cases. It is impossible to admit the independent existence of these manifestations which are so closely related to each other; unluckily the connection is not always visibly traceable. The development of chronic muscular inflammations in the neck, as in other regions of the body, is always very slow. It may take not only months, but sometimes even years before they provoke pain. Thanks to this latent and insidious progress, the organism gets, so to speak, gradually accustomed to their presence. These inflammations will produce symptoms only when they have attained a certain degree of development, a period which may vary considerably in different individuals. In order to provoke an attack of headache, it is often necessary for an occasional exciting cause to be added to the already existing organic one. This new element produces a state of congestion of these myositic deposits, and may be provoked in a direct or reflex way by all the various causes, which we know usually give rise to an attack of migraine or common headache. I intend to treat, elsewhere, of this extremely interesting matter, which I have here only alluded to.

Region of the Trunk.—Myositis of the trunk, like that of the neck, gives rise to different processes. A strain in the small of the back, the Frenchman's *"tour des reins,"* is spoken of as an acute affection of traumatic origin, characterized by a sudden, continuous pain, sometimes so exaggerated on motion, that the patient is obliged to remain more or less quiet. Here, again, we have a laceration or rupture of some muscular fiber, sometimes only a violent stretching of them, followed by an inflammatory reaction. These are excellent cases for massage. In two or three sittings, sometimes in only one, the masseur is able to overcome affections which seemed intractable. It was in a case of this kind, communicated to the society in Lyon in 1837, that Martin was able to achieve wonderful results and revenge himself on one of his colleagues who was skeptically inclined towards massage. Lumbago is a painful affection which, as the name implies, has its seat in the lumbar region or in the loins. It is most frequent in its acute form, and is then either of rheumatic origin, or only a pain due to a cold, the true nature of which is not known. The terminology needs to be definitely settled; strain in the back and traumatism, lumbago and rheumatism are indifferently spoken of. In all probability the cause varies in the different cases. Massage yields almost as good results in this affection as in the troubles we have just described. As regards the chronic form it is one of the diseases we frequently encounter. In some cases there is only a common chronic muscular rheumatism left to itself or treated in a wrong way, but most frequently we have to deal with a real myositis, in a different stage of development. Most pathologists classify lumbago among the forms of rheumatism.[10] They do so because they entirely ignore its frequent myositic origin, whereas in reality, in these cases, the rheumatism only acts as the causative factor. In a great number of cases which we have had to treat, we were dealing with myositis whose deposits were often very numerous. These deposits may be discovered in the prevertebral muscles, in the sacrolumbar muscles and in the great dorsal muscle. As long as an area of loss of elasticity or a resistance remains, we must continue the massage laboriously, in order to prevent relapses. Only in young people can we, without fear of return, leave a little remainder to nature, which, as in other parts of the

*Wretling, Helleday, Prof. Henschen, Bumm, and lately the eminent nerve specialist, Prof. Edinger, in Frankfort, have arrived at the same result. The last one has published his views in an extensive article on headache and migraine, inserted in the *Deutsche Klinik*, as well as lately through his assistant physician, Dr. Auerbach (*Sammlung Klinischer Vorträge*, No. 301).

body, owing to the increased vitality imparted to it by the treatment, will often disappear in a short time.

M. L., thirty-four years old, has complained for many years of pains in his back, particularly in the right side. Starting in the upper part of it, the pain had slowly extended to several parts, which did not seem to be affected at the beginning. Electricity, warm baths, vesicatories, hydrotherapy, were tried, but in spite of these the pains became so violent that they often compelled the patient to remain absolutely quiet for weeks. In the intervals he walked with his head constantly bent forward, carefully avoiding everything that was able to excite even the slightest tension of the affected muscles. He experienced sensations as though his chest were being constricted by a vise. Obliged always to assume the same position in the bed, he could not sleep. His general state of health declined, and he was obliged to give up his position as accountant. Last year he tried gymnastics, but without any success. Different diagnoses were made; rheumatism, neuralgia, spinal irritations. No sensitive point along the vertebræ on pressure or touch. The long muscles of the right side of the back, appear even to the eye more bulky than normal. The increase of volume ceases in the upper part of the scapular region, where the muscles seem to be normal. On exerting more powerful pressure, one discovers some deposits of myositis in the lower part of the long muscles of the back. The size of these deposits varies from that of a large pea, to that of a walnut; they present all stages of development of myositis, from puffiness to that of real sclerosis. Frictions of the belly of the muscles. Petrissage of the induration; marked relief after forty sittings; movements not very painful; the patient can walk without too much difficulty. Sleeps better; he can rest on the parts which were formerly the most painful. After a little more than two months the muscles had regained their normal state; the deposits had almost entirely disappeared, and the patient was able to sleep well and to resume his occupation. No recurrence after ten months.

There are other forms of myositis in the trunk which are not spoken of, and which, however, are nevertheless no less painful than those which I have just mentioned. They have their seat in the anterior wall of the abdomen, and are sometimes very hard to detect by the inexperienced examiner.* If the swellings are situated in the lateral parts of the abdominal wall they are often yet more difficult to discover. It is then necessary to turn the patient over to the side opposite the one in which the supposed deposit is seated. In this way, the bowels falling over to the other side, the muscles are thoroughly relaxed, and the examination is made easier. These masses, in the same way as deposits of myositis and panniculitis seated in the wall of the chest, can produce intercostal neuralgia, may give rise to gastralgia, symptoms simulating chronic gastritis, enteralgia, cystalgia, and even pain in the region of the ovary, thus simulating ovaritis. Four years ago I treated in this city an elderly lady, who, in addition to a dull pain in the lower part of the abdominal wall, complained of a very frequent micturition and constant vesical pain. Fortunately for my patient, the indurated nodules, discovered in the lower part of the abdominal wall were superficial, and easy to get at. After six weeks' massage, when almost cured, she was obliged to interrupt her treatment. She was then able to attend her business (ticket-receiver), as well as before. I saw her a few months afterwards; the improvement persisted, and was even more decided. This fact seems to confirm an opinion supported by Hartman,[11] according to whom cystalgia is very often of reflex nature. Since coming here from Europe, I have treated not less than three cases where the symptoms due to muscular inflammations in the epigastrium simulated a stomach affection, and had been treated as such. While trying to get at the stomach, in order to examine it, the patient complained of a very marked pain in the abdominal wall, contracting it beyond measure. At the same time I discovered, seated in it, and in the rectus muscles, a hard, big lump of rather flat form, the size of which in one case was that of the hand of a child. The usual internal treatment applied had, of course, been without effect (in one case the stomach had been washed out by a stomach specialist for several weeks). The treatment of the deposits with massage was followed by a permanent disappearance of all symptoms attributed to an idiopathic stomach trouble. I have already alluded to the frequency with which a muscular inflammation or panniculitis in the right side of the abdominal wall is mistaken for acute or even chronic appendicitis. Here it is particularly necessary for the physician to be very cautious, and exhaust all diagnostic resources. In the following case an error might easily have been made had the consulting physician been less on his guard. Some years ago I was called to see a gentleman who complained of a rather dull pain in the right side of the abdomen, which made it impossible for him to lie on this side. One of the best known surgeons of this city declared that the affection had nothing to do with appendicitis, but was unable to diagnose the real nature of the disease. On examination it was not difficult to discover in the right hypogastrium, seated in the integument, and in the neighborhood of the appendix, a swelling, forming a rather flat lump, and of the size of a silver dollar. It was very elastic to the touch, but the patient complained of a great deal of pain on pressure. I made the diagnosis of panniculitis, but having massaged the lump for a while, and reduced it in size, I found that, not only the adipose tissue but the underlying muscular layer also was involved in the formation of the lump, so that there was a combination of myositis and panniculitis. After massage (slight friction), had been applied for three or four weeks, the deposit disappeared. The patient is now able to lie on one side as well as the other, and has since then been entirely rid of his trouble. Of all cases of myositis affecting the trunk, the most annoying are those in which the trouble is located in the abdominal wall. Not only do they give rise to difficulties in diagnosis, but they are also very difficult to overcome; their treatment is painful; the deposits move under the finger, because the mass of intestines is continually shifting. We can only obtain a relative fixation of the parts by telling the patient to hold his breath as long as possible.

Upper Extremities.—Myositis of the shoulder and the arm. Chronic myostis is very frequent in the arm. It is often found in the deltoid muscle, and then almost always in the neighborhood of its insertion into the humerus, with a tendency for the pain to radiate down the arm into the hand.* Be-

*This is particularly the case when the patient is very fat, or sensitive to touch, as we find especially with hysterical subjects.

*Sometimes I have observed myositis of the deltoid giving rise to symptoms in distant parts of the arm, just as muscular inflammations in the neck do in the forehead. But here they more often assume the character of paresthesia or something like a partial paralysis. According to the greater or less proximity of the myositis, one or the other of the nerves inervating the arm and the hand is affected. How many times have I met persons who complain of numbness, formication, pricking sensations, etc.,

sides this, I have found it affecting all muscles of the arm except the biceps, this one being the seat of traumatic myositis only. In the forearm myositis much more frequently affects the muscles that are inserted into the external condyle (extensors and supinator longus), than those inserted into the internal condyle (flexors and pronator longus). With regard to this I report here a case of great interest. M. S., 24 years old, native of Germany. Very robust and healthy looking. Experienced, at the age of eighteen, pains in the upper part of the right arm; the physician consulted made the diagnosis of rheumatism. In the spring of 1893, the pains became very violent, but yielded for some weeks to treatment by massage, electricity and saline baths. In the autumn of 1894 the pains reappeared, and with greater violence than they had ever done before, so that the patient was not free from them even during the night. In this state I found the patient, when he came to see me in Ragatz, the following summer. The previous winter a well-known surgeon had advised him to undergo an operation, which was declined, in the belief that there had formed in the muscle a scar, after possible rupture of some of its muscular fibers. The pains were of a dull character, and not always of the same intensity; they were particularly violent at the approach of cold and damp weather. They were always confined to the same spot, and did not radiate along the arm. The patient also complained of weakness in his arm, which was steadily increasing, so that finally he could only move it with difficulty. The weakness had, when I saw him, developed to such a degree that he was unable to raise even light weights, such as a glass of water, or he would drop it after some moments. Penholders or similar light objects dropped out of his hand with ease. On account of this affection he was pronounced unfit for service by the military authorities, and was exempt from military duty. On inspection no external difference could be detected between the two shoulders. On palpation the right shoulder felt a little flabby. In the lower part of the shoulder, not far from the inferior insertion of the deltoid muscle, and seated rather deeply in its substance, there were two different deposits of myositis. The larger one of these was situated not far from the external border of the muscle (it was of the size of a walnut), whereas the other one, smaller and flatter, was located a little lower down. Both were in the last stage of the disease; that is to say, in the stage of induration; painful only on strong pressure. As I had only three weeks at my disposal before leaving Ragatz, I was obliged to resort to two sittings a day (during the last six days up to three sittings), and to work very energetically. Even after one week the patient felt a little better, and could pass the night without being much disturbed by pain. When I left him he was quite well, and had not felt any pain for about a week. He also maintained that the former strength of his arm had entirely returned. Two years afterwards I received word from him, learning, with pleasure, that his condition left nothing to be desired. That writer's cramp is most often due to chronic myositis of the arm, and particularly to that of the forearm and the hand, I have shown in an article published in the *New York Medical Journal*, March 12, 1904, and I refer the reader to this publication.

Lower Extremity.—Myositic deposits are found in all the gluteus muscles, but while relatively rare in the gluteus maximus and minimus they are of most frequent occurrence in the gluteus medius. Myositis of the psoasiliac muscle is rather rare, and I have already reported one of the very few cases I have seen during the very long time I have practised massage. I am now going to speak of the relation existing between sciatica and myositis in the gluteus medius or the peroneal muscles. Rheumatism produces in many cases of sciatica a special myositis, which comes on either before or after the neuralgia or the inflammation of the nerve itself, or simultaneously with it. I have carefully examined all the muscles situated along the upper course of the sciatic nerve, and to my great surprise only one of these seems to be the favorite seat of the concomitant myositis. It is the gluteus medius, and particularly that portion of it which corresponds to its upper insertion. If, however, we follow the course of the nerve downward, we sometimes notice deposits in the calf, on a level with the peroneal muscles. The deposits may extend along the entire length of these muscles, but their maximum development is most often found towards the lower insertion of the muscle. This explains, in my opinion, the particular pain which persons, affected with sciatica, real or not, very often complain of in just this last region. It is difficult to determine which one of these two phenomena, neuralgia or myositis, is first produced. Sometimes they are simultaneous, the same cause, namely, rheumatism, provoking each of them. At other times, at the onset, the nerve alone seems to be affected, but the muscle or muscles soon become involved in their turn. Finally, in certain cases I have noticed that the gluteus medius or the peroneal muscles were alone affected, and that myositis produced all the symptoms which are generally attributed to sciatica alone.* This may account for the fact that in many cases we are liable to err and that, if we were to diagnosticate the inflammation of the gluteus medius from the very beginning, we could succeed in impeding its further development by appropriate treatment, and thus prevent the propagation of the irritation to the sciatic nerve. In these cases a real compression may be produced by the inflamed muscular fibers, analogous to that sometimes, although rarely observed, in cases of tumor or foreign bodies (hard excrements) pressing on the same nerve, and giving rise to sciatica. I have had to treat, and with success, a certain number of cases in which I have used only massage on the muscle proper, without paying attention to the nerve itself. In one person, among others, laid up for six months, and in whom all classical means had been employed, I was able to obtain complete cure in less than six weeks by this procedure alone. In this case the sciatic nerve did not present more than physiological sensitiveness on pressure, but pressing on the muscle in the neighborhood caused the patient to scream out, and leap in the air, to the great surprise of the patient himself, and of the physicians who were called in consultation with me. This peculiarity is most frequently not noticed, but nevertheless it plays a most important part in the treatment. Many cases of sciatica remain uncured, because the possible presence of a myositis

in the hand, when the real cause was a muscular inflammation of the deltoid. I have treated several cases of this kind, but I remember particularly a lady who consulted me some years ago, and whose only complaint was a most unpleasant sensation of cold with formication in the thumb and its two adjoining fingers. I found a lump in the deltoid muscle pressing slightly on the radial nerve without producing any abnormal sensation in the muscle itself. Various treatments applied, in the neighborhood of the hand had been employed without any success, whereas massage and suppression of the myosotic deposits in the above muscle brought about a permanent cure. I have also seen the same phenomena produced in the lower extremities.

*To this last pathological condition I have given the name of false sciatica.

developed in the neighborhood of the sciatic nerve has not been taken into consideration. Moreover, it is well to remember that this muscular inflammation may exist at the beginning only in the form of a simple puffiness, hardly perceptible, and slightly sensitive to the touch, and quite frequently very difficult to detect by an unpractised finger. What I have just spoken of refers only to myositic deposits. But it is not out of the ordinary to find deposits, giving rise to false sciatica, that are of a mixed nature like those formed in other parts of the body. Some of them may correspond to those of an exclusive myositic origin, whereas others are found to be of a panniculitic nature, and still others, these more rare, exhibit in the same nodule the presence of both these varieties. This is distinctly shown by the following case which I report here on account of its great interest. A young nurse, who was last year (1903) operated upon (digital stretching) for sciatica without avail, was sent to me last spring by Dr. Schwyzer of this city. On examination, I found not only a big mass of exclusively myositic origin in the gluteus medius, and seated close to the spot where the sciatic nerve emerges from the pelvis, but also one in the same muscle a little lower down, and of a mixed nature (myositis and panniculitis). Moreover, there was another deposit, this one of a more soft consistency than the others (panniculitis), situated in the fossa poplitea, and pressing on the external branch of the sciatic nerve. Furthermore, a rather hard lump (myositis) was discovered in the lower portion of the long peroneal muscle. No difference in the size of the lower extremities was noticeable, but the one corresponding to the side where the affection was seated felt distinctly more flabby than the healthy one. When, after six weeks of massage, I was obliged to interrupt the treatment on account of my departure for Europe, the patient who had been suffering a great deal, and could walk only with difficulty, limping a great deal, was in greatly improved condition, and could sometimes walk without any pain for days, excepting the discomfort felt in the popliteal region. Most of the lumps had disappeared. When I saw her again (end of October last), she told me that she had passed a rather good summer; that she scarcely felt anything in the upper region of the sciatic nerve. The only noticeable trouble that remained was the above-mentioned pain in the popliteal fossa, particularly in wet weather. This caused her to limp a little again, but after a month's treatment this pain also became very slight.

Myositis in the thigh nearly always has its seat in the quadriceps muscle. Sometimes it is also found in the aductors. It is then almost always of traumatic origin, and we see it from time to time in those who ride horseback. It is very frequent in all the muscles of the leg, and is especially so in the muscles in the region of the tendo-achilles, where its favorite seat is the inferior third and inner side of the muscles forming the lower part of the calf, the pain often radiating upwards into the calf, and sometimes into the whole leg. These last deposits generally occasion swelling of the adjoining parts, especially in the evening, when the patient has been standing or walking a great deal during the day; the tumefaction then often constituting a real cushion, which very frequently gives rise to a wrong diagnosis, as I have already mentioned. I have seen enormous swellings of this origin, with deformities of the leg, as a consequence of this disease, and time and again I have observed that the invalid, dragging his leg, was obliged to give up walking after only a very short time. Massage is very painful in these cases (particularly on the internal side), but always yields the most satisfactory results. Besides the patient whose case I have reported, among a great number of others, I recall one in particular, namely, a chambermaid, whom I treated several years ago in Paris. During the greater part of the day this girl was obliged to stand. The swellings had assumed such proportions that her legs, which were quite well formed by nature, had taken an almost cylindrical shape. When she came under my observation she was about to leave her position, on account of the disability. After more than two months' daily energetic massage (she had two big, hard lumps on one leg, and three on the other), she was relieved of her swellings, and the legs had regained their natural form. She was then able to walk as well as before, and has since always remained well. The not very rare affection named *tarsalgia* or *talalgia*, characterized by a pain in the region of the heel, and on which Dr. Vincent has of late published a very good article in the *Semaine Medicale* is, in my opinion, often due to a chronic myositis seated in the plantar muscle, corresponding to its insertion in the heel. In these cases massage yields a most satisfactory result. as also in those not infrequent cases where a deposit in the sole of the foot has been taken for a flat foot. Lastly, I will add that muscular inflammations of the leg, and particularly those of the calf, are sometimes a cause of lack of steadiness of the ankle joints, the muscles, like those fallen into atrophy, on account of their diseased and weakened condition not being able properly to hold together the respective extremities of the bones that constitute the joint. These are often disposed to separate, and often give rise to sprain.

When examining it is of great importance to relax the muscle one is palpating, as otherwise it may sometimes be difficult to differentiate a muscular inflammation, particularly in its initial stage, and a normally contracted muscle. To that end, I speak here only of the limbs; one must tell the patient not to contract his muscles. The arm should be supported by the left hand of the physician. The muscles of the leg become sufficiently relaxed for our purpose if the patient is lying on a couch or is sitting in a chair, his heel resting on another chair.

As concerns the treatment of chronic myositis, I think we can do no better than to reproduce what Dr. Adler says in the above-mentioned article. "The well-known hot baths and springs, electricity, the internal administration of iodides, gymnastics, and the host of other remedial schemes that have been recommended, will produce no lasting result. It is safe to say that they will scarcely touch the local lesion, which is our main objective. The rheumatic infiltrations and indurations can be best dealt with by proper massage." Rheumatism constituting a predisposing cause of chronic myositis, as already mentioned, it is useful to supplement massage by thermal baths, administered when the massage treatment is over, and in order to prevent relapses. Among all affections amenable to massage, there is, I think, none which taxes the patience of the patient as well as that of the masseur, so much as the treatment of well-developed deposits of myositis. This is particularly the case when one has to deal with a mass which has reached the last degree of development, a muscular induration. Such a one, sometimes of the consistency of cartilage, may, particularly in old people, demand up to two or three months' energetic treatment before it has entirely disappeared. In order to prevent relapses one should, if possible, continue the treatment until palpable changes are completely removed. As I have already mentioned, this rule is subject to exceptions, as in young people one may, without harm, leave a small

residue, which by massage has been reduced to a soft condition, in the hope that nature will remove it.

The treatment comprises friction, more or less energetic according to the consistency, or, what is the same, the age of the deposit. Where the muscles are accessible to petrissage, as in the upper border of trapezius, this manipulation should be employed. For massage of the muscular deposits the thumb exclusively is used, and the development and strength of the latter plays a most important part in the treatment of a chronic myositis, the success depending greatly upon this circumstance.

RADICAL OPERATION FOR THE REMOVAL OF A BULLET WEIGHING 70 GRAINS, EMBEDDED IN THE INTERNAL WALL OF THE MIDDLE EAR, WITH DECIDED IMPROVEMENT IN THE SUBJECTIVE SYMPTOMS.*

By M. D. LEDERMAN, M.D.,
NEW YORK.

ADJUNCT PROFESSOR DISEASES OF THE NOSE AND THROAT, NEW YORK POLYCLINIC; FELLOW NEW YORK ACADEMY OF MEDICINE; FELLOW AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY, ETC.

Foreign bodies in the external auditory canal and cavity of the middle ear are not rare. The former, as a rule, are introduced by the patient in early life, while in the second variety the disturbing element reaches the tympanic cavity by faulty technique. In the third class, to which the subject proper of this brief contribution belongs, the extrinsic element finds its resting place by more violent force.

Among the numerous cases that have come under my personal observation, I mention, in passing, a few instances in which, unskilled manipulation drove a glass bead, a cylindrical piece of glass, a mass of silver foil, and a pebble through the drum membrane into the middle chamber. Infection had occurred and purulent discharge existed at the time of my examination, but this soon ceased after the irritating factor was removed and mild antiseptic irrigation was employed.

In the case of the pebble, the foreign body was found in the middle ear of a boy twelve years of age. It had been in position for over two months and owing to repeated attempts for its removal through the external auditory canal by different physicians the soft parts of the ear were much swollen and inflamed and considerable granulation tissue had formed around the stone, which had buried itself in a pocket at the junction of the membrane tympani with the posterior wall of the external canal. At one of the city hospitals, an incision had been made behind the auricle, but the pebble was not found. It was impossible to locate the object by inspection, but its position was detected by means of the probe. The surrounding granulation tissue bled profusely on being disturbed, and though manipulations with the dull curette were carried out the stone could not be dislodged from its pocket. Desiring to avoid further traumatism, the patient was etherized and an incision made along the auricular attachment over the mastoid. The membranous canal was detached anteriorly, and the pebble, which was about half an inch in length by a quarter of an inch in breadth, was removed quite easily. After curetting away the granulation tissue, the incision was sutured and the canal packed with iodoform gauze. The wound healed kindly and the aural suppuration ceased in a short time. Good hearing followed the closing of the perforation in the drum membrane. This history is cited merely to call attention to the necessity of rather heroic treatment which could have been avoided, if delicate and appropriate technique had been carried out at the first examination.

The following report is the history of the patient from whom this paper derives its title.

Anna S., colored, 24 years of age, presented herself at my clinic at the Manhattan Ear and Eye Hospital, February 4, 1904. She stated that three years ago she was shot in the left side of the head at close range, the bullet entering the skull immediately above the tragus. The weapon used was a 32-caliber revolver and was held within six inches of her head. Following the injury she was unconscious for three or four weeks, and for a lengthy period could not appreciate her surroundings. At the time of the injury an attempt was made to find the bullet, but without success. Vertigo promptly ensued and became so severe that the patient was unable to stand alone. (This symptom existed up to the time of the radical treatment.) Facial paralysis of the left side soon followed the injury, and at the time of my initial examination was quite in evidence, though the patient informed me that her face was much better than three years before. Suppuration of the left ear developed shortly after the shooting, though pain in the ear was not a disturbing element. The discharge became bloody and foul-smelling after a time, but no retention symptoms were observed.

With the good ear closed, the watch could not be heard at all with the left ear, but the loud voice was faintly understood. Bone conduction was decidedly positive. Inspection of the soft parts revealed a small scar, pale in color, just above the tragus. The external auditory canal was obstructed by a pale pinkish round tumor, which almost closed the opening. The growth was fibrous in its resistance to the probe, and foul-smelling pus escaped around its free surfaces. As it was impossible to see beyond the growth, the latter was immediately removed with the aural snare under cocaine anesthesia and adrenalin. The fibrous polyp was almost an inch in length and half an inch in breadth at its anterior surface. Free bleeding followed and was arrested only after tight packing with sterile gauze. Examination then showed a large perforation of the posterior half of the tympanic membrane, the edges of which were covered with granulations, and the opening in the drum seemed to be filled with a darkish mass which resembled a blood-clot. On closer observation, the substance appeared of a bluish color and gave a distinct metallic sound to the probe, showing it to be the bullet *in situ.* The leaden mass extended behind and above the posterior and superior boundary of the annulus tympanicus. It was impossible to move the flattened bullet from its posi-

*Read before the Harlem Medical Association, February 1, 1905.

tion by means of a strong pair of forceps or a curette, though considerable force was used. I only succeeded in bringing away small chips of lead. The foreign body was embedded in the internal wall of the middle ear, causing pressure on the cochlea, horizontal semicircular canal, and facial nerve.

The radical operation was performed about two weeks after the first examination, as the patient was presented at the Otological section of the Academy of Medicine with the bullet in position. The usual incision was carried along the auricular attachment over the mastoid process, and on elevating the periosteum small dark spots were seen over the bony surface where particles of lead had spattered as the molten mass had entered the skull. (The direction of the bullet must have been downward and backward, as the anterior surface of the middle ear was found free from lead.) The mastoid opening was kept close to the posterior canal wall until the antrum was entered. No pus was found in this cavity, but quite some granulation tissue was curetted away. The bridge of bone separating the canal and middle ear from the mastoid antrum was then removed, revealing the large mass of lead occupying the posterior surface of the internal wall of the middle ear. The remaining portion of the drum membrane, together with the diseased malleus and incus, was extirpated. After repeated unsuccessful attempts to lift the bullet from its bed I employed the chisel and mallet in a cautious manner, to avoid entering the cochlea and semicircular canal. By this method I was able to procure seventy grains of lead which came away in shavings. Some of the smaller pieces were lost in cleansing the cavity. The remaining coating of lead was taken away by means of the bone spoon. After thoroughly removing existing disease in the middle ear, the usual Koerner meatal flap was placed in the posterior bone opening and the skin wound sutured. Iodoform gauze was placed in the auditory canal.

There was very little reaction following the operation and though two stitch abscesses occurred in the upper portion of the wound, the healing continued without further annoyance. About the fifth day the patient was able to sit up in a chair and volunteered the information that her dizziness was much better. There was some aural discharge for three weeks after the surgical treatment, and same was treated after the dry method with good result. No evidence of lead was seen along the superior or posterior canal walls, proving that the bullet must have found its way along the free meatus to its final resting place. Two weeks after operation the ordinary speaking voice was plainly heard in the ear, with the good ear closed. The patient was able to walk quite well without support, an act she had not been able to accomplish since the injury three years before. The facial paralysis was slowly improving without additional treatment.

The interesting features in the above case is the presence of a foreign body (32-caliber bullet) lodged in the internal wall of the middle ear for a period of over three years, causing chronic suppuration, tissue proliferation, facial paralysis, and marked disturbance in equilibrium *without* more serious complications. When we consider the relative distances from the middle ear cavity to vital structures, it is surprising what active protection nature's resistance exerts at all times. Here we have an instance of a wound at close range, from a large caliber revolver, with but local disease and symptoms that may be assigned to direct pressure from the foreign body. It is but another corroboration of the anatomical truism, that a negro skull *does* withstand considerable traumatism without serious sequences. Had this injury been inflicted upon a Caucasian skull, a similar report of the case would surely never have been recorded.

AORTIC REGURGITATION WITH CHRONIC MILIARY TUBERCULOSIS IN A MAN TWENTY-TWO YEARS OLD.

By MEDWIN LEALE, A.B., M.D.,
NEW YORK.

On July 5, 1904, the following case came under my care at the Roosevelt Hospital, Out-Patient Department. Charles O'L., age 22 years, single, a native of Italy, a salesman by occupation, came to me with the following history: Family history excellent so far as could be ascertained. Four years ago he had an attack of acute articular rheumatism. He also had a bad cough about four years ago, which lasted several weeks, and during which time he spat up a few teaspoonfuls of bright red blood. Between this time and another attack of cough, two years ago, he informs me he felt perfectly well. This second attack of cough lasted somewhat longer than the first, he expectorated more abundantly, and had another hemorrhage, perhaps larger than the first. His habits of life have been excellent. He is temperate, and gives no venereal history.

Present illness: For the past three weeks he has had a troublesome cough, with mucopurulent expectoration, which at times was tinged with blood, but has had no large hemorrhages. He has not been troubled with night sweats, nor has he lost any appreciable amount of flesh. He has had no headaches, no dizziness, no flashes of light before the eyes, but has, however, been troubled with slight dyspnea, palpitation, and oppression on exertion. He has had no attacks of angina pectoris, nor anginoid pains of any sort. He has had no swelling of the feet. His appetite has been rather poor, but his bowels have been regular. In fact, his general condition has been very fair, and he now comes to consult only about his cough.

Physical examination: A man rather under the average height and weight, although fairly well nourished. The color of his skin is rather pale, as are also his mucous membranes. There is no distinct cyanosis. There is a very noticeable pulsation of the peripheral arteries, especially the carotids, temporals, brachials, and radials. The capillary pulse is well marked. The pulse is of large volume and collapsing (Corrigan pulse), but regular and of proper frequency. The arteries are not thickened to any appreciable extent. On inspection of the chest there is noticed a diffuse heaving impulse of the whole præcordium. On this account it is difficult to locate the apex, which appears to be in the lower part of the fifth interspace, about one and a half inches outside the mid-clavicular line. On palpation, besides this heaving impulse over the lower præcordium, a diastolic thrill is imparted to the palpating hand above the middle of the sternum. On percussion the area of cardiac dullness is increased downward and to the left, and somewhat to the right of the sternum, though to a less marked extent. On auscultation over the second right interspace a harsh, high-pitched diastolic murmur is heard, which is transmitted downward. The second sound is indistinct and hard to isolate from the murmur, which occupies a greater part of the diastole. Over this same area, the second right interspace, a rough systolic murmur may be heard, which is

transmitted upward into the neck. At the apex a rather loud presystolic murmur is heard, in all probability the so-called Flint murmur.

On examination of the lungs, the expansion of the upper part of the left lung is found to be not so good as that of the right side. There is little appreciable change in fremitus on palpation. On percussion there is considerable dullness over the left apex in front and behind, and on auscultation the breathing is feeble and numerous fine crackling râles are heard. A specimen of the sputum showed numerous tubercle bacilli.

This case seems of special interest, as the combination of aortic regurgitation and chronic miliary tuberculosis appears of rather infrequent occurrence. It is also rather unusual to see a case of well developed aortic regurgitation in so young a subject, most of the cases occurring in those of middle age or who have passed the prime of life, in whom there is often more or less arteriosclerosis. Whether in this case the valvular lesion was secondary to the miliary tuberculosis, being part of the tubercular process, forming tubercles on or near the segments of the valve, or whether it was an entirely distinct pathological process can, of course, only be cleared up by necroscopy. In support of this hypothesis Tripier claims, although on more or less theoretic grounds, that acute tuberculous endocarditis is nearly constant in cases of general miliary tuberculosis, and we are also familiar with the results obtained by Michaelis and Blum, who demonstrated the presence of tubercle bacilli in lenticular growths on the valve segments in rabbits suffering from tuberculosis. Demme, Mariani, Pollack, and others have demonstrated tubercle bacilli in heart tuberculosis.

107 West Seventy-fourth Street.

A CASE OF CICATRICIAL STRICTURE OF THE ESOPHAGUS.

By A. B. ATHERTON, M.D., L.R.C.P. & S. (Edin.),
FREDERICTON, N. B., CANADA

As cases of cicatricial stricture of the esophagus are uncommon, and their treatment often difficult and more or less unsatisfactory, I have thought that the report of one which has recently been under my care might be of some interest.

W. B., age 26, male, first came to me for treatment on October 27, 1903, with the following history: Five months before he had swallowed some lye by mistake for whiskey. The usual pain, dysphagia, etc., followed. At the end of three months his condition became so serious that he resorted to one of our provincial city hospitals for treatment. He says a tube was passed down his throat a few times and his "stomach washed out." Deriving no benefit, he returned home after three weeks.

When first seen by me he was very much emaciated, and could swallow liquids only through a glass tube. Any attempt to drink from a cup would set up a severe fit of choking and coughing, while most of the liquid was regurgitated.

On passing a probang, I found that it brought up at the lower end of the esophagus, but I succeeded in getting an olivary French bougie of about two millimeters diameter through the stricture. In the course of a week about double this size could be introduced, but after this no effort of mine enabled me to increase the amount of dilatation. He was then, however, so far improved as to be able to drink slowly from a cup without choking.

November 19: Chloroform being given by Dr. McGrath, I opened the abdomen and drew up the stomach. After packing around with gauze, I cut into the stomach in the line of the abdominal wound and washed it out with boiled water. Then I tried to pass an olivary bougie from the mouth to the stomach, but did not succeed, largely because it was too flexible, I think. I therefore took the whalebone handle of an ivory probang and covered the rough end with a short piece of small rubber tubing secured by a silk thread wound around it, and was able to pass this through stricture. On bringing the end out of the stomach wound, I tied a stout silk plaited cord to it and withdrew them through the mouth. Then fastening this cord, by means of a silk thread to the tip of a French olivary bougie of 4 millimeters, I drew upon the end of the cord below until bougie and cord appeared. With these occupying the esophagus, I drew them back and forth a number of times. I then tried to get a larger bougie in alongside of the silk cord, but failed, the stricture not having yielded to any extent.

I now therefore left the silk cord and bougie *in situ*, and closed the wounds in stomach and abdomen.

After a few days' continuous dilatation, a larger bougie was easily got in, and by the end of ten days a No. 22 French bougie passed.

December 1: On leaving out the bougie for fifteen or sixteen hours, it was found that considerable contraction had taken place, and I resumed continuous dilatation, the instrument being removed for two good meals in the twenty-four hours, which were taken readily and with much relish.

December 15: Is able to be out of bed. Abdominal wound all healed. Gaining rapidly in flesh. A solid red rubber bougie, about a foot in length and slightly tapering at its lower end, is kept most of the time in the esophagus. It is one centimeter in diameter, and its upper end lies at the junction of the pharynx and esophagus, and is secured by a silk thread fastened to a tooth or one ear.

December 19: Patient left for his home, 100 miles away, wearing the bougie, and able to withdraw and introduce it himself.

On March 19 following, he returned to me because he had failed to pass his bougie after leaving it out several hours. I was able to introduce at once a somewhat smaller one, and in a day or two the former size. He then returned home.

I heard from the patient in November last. He is obliged to continue the daily use of bougie, otherwise the stricture soon contracts.

It is, I think, doubtful whether any better method of dealing with an obstinate cicatricial stricture of the esophagus can be employed than this one of Abbe's. A small rubber tube drawn through the esophagus on the stretch and left there to cause dilatation by its elasticity, is said to answer very well in opening up the strictured portion, after a preliminary gastrotomy. In our case, however, after the use of the cord and bougie in a seesaw fashion, dilatation was effected as readily and quickly as one could wish by retaining the ordinary olivary urethral bougie in the canal. Previous to the use of the string, no headway of any consequence was gained, while subsequently dilatation of the stricture went on easily, even though at the time of operation not much, if any, larger instrument could be got through it. I suppose the friction set up a softening process, which allowed the dilatation to take place afterwards.

Although one in this man's present condition cannot be said to have a very comfortable life, still we think he is in a much better state than one who has undergone a gastrostomy and is obliged to feed himself through a gastric fistula.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR

PUBLISHERS
WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 11, 1905.

THE JUBILEE OF LARYNGOLOGY.

ON the seventeenth of the current month, Señor Manuel Garcia, for many years a teacher of singing in London, where he now resides, and the first man who ever saw fully the interior of the living larynx and the vocal cords in action, will celebrate his one hundredth birthday. This month is also the semi-centennial of laryngology. This is not the first instance in which medical science has been benefited by the work of one not directly connected with it, or in which the direct results of a discovery have been overshadowed by the indirect. Many investigators before Garcia's time had endeavored to obtain a view of the interior of the larynx in the living subject, but most of them had been working from the standpoint of the anatomist, or had looked upon their task as an interesting problem in physics. Some of them had come very near success, but no one of them had solved the problem in the sense in which we understand laryngology to-day. Garcia seems to have been unaware of these previous attempts, or if he did know of them they did not condition his own thinking. He apparently took up the question solely from the standpoint of the teacher of singing, who was naturally desirous of viewing the structures so closely related to his own life work. Almost as an inspiration, the conception of the physical laws involved came to him. Assuring himself of the practicability of his own ideas, he presented, in due time, his memorable paper to the Royal Society.

The early years of the new science were somewhat unpromising. The profession was largely hostile to its claims, and it was not until Czermak made his brilliant laryngological demonstrations in the medical centers of Europe, that it was fully realized that a new specialty had been created.

While every specialty has been accused of extreme views and of a tendency to detach itself from general medicine, there has been in each instance a faithful band of adherents, which has never forgotten that the whole is greater than any one part, and which has insisted that a specialty can never separate itself from general medicine without results disastrous to both. So it has been in laryngology, which has made illuminating contributions to general medicine.

The technical directions laid down by Garcia for laryngoscopy, were the solution of a long-debated problem. At first his "little mirror on a long handle" was regarded more as a physiological toy than as a key to the understanding of diseases of the larynx and the establishment of the latter on a logical basis of pathology and classification. But the great value of the laryngoscope soon became apparent, and it was seen that its revelations were likely to clear up some of the uncertainties of general medicine, particularly with reference to the question of nerve distribution in the larynx, and muscular action in this general area. From this beginning has grown an orderly branch of medical science with its own special literature, institutions, and teachers. With the passing years the work of Garcia has been seen in its true relations. Happily he has lived to see it fully appreciated, and has reaped the reward of his labors amid the applause of his own day and generation.

It is also a pleasing thing to view the cordial relations which have always existed between him and the London profession. By it he has been and still is highly esteemed. He has shared indirectly in many of its triumphs, and has been the recipient of much honor at its hands. On his part he has contributed in addition to his great discovery, the endowment of a charming personality, a mind with undimmed recollections, and a marvelous physical and mental activity which have made his later years, not a tedious waiting for the end, but a time of active interest in the world's affairs. To him the MEDICAL RECORD extends its heartiest congratulations. Not a false note has sounded in the acclaim which has come to him from all the quarters of the earth. It has been sincere, spontaneous, and unrestrained, and all know that the kindly feeling is cordially reciprocated by the great master.

THE HOME AND THE TUBERCULOSIS PROBLEM.

THE first annual report of the Henry Phipps Institute contains a series of addresses on various phases of the tuberculosis problem delivered under the auspices of the Institute.

Dr. William Osler, on December 3, 1903, in one of these addresses, considered the home in its relation to the tuberculosis problem. The fact is being borne with increasing force upon all earnest students of the tuberculosis problem, that the home is the stronghold of the disease, and that in order to fight it with any hope of ultimate success, it must be met and grappled with in its strongest fortress. Of course the most radical and iconoclastic plan would be the most effective, that is, to destroy all rookeries and unhealthy buildings, and to erect in their stead airy, well-ventilated, and well-lighted buildings. So long as overcrowding and living under obviously unsanitary conditions are allowed it will be impossible entirely to eradicate consumption. In the course of time, when the mass of the population is educated to that point, unhealthy buildings will disappear. This result, however, will not come at once, but will be a matter of years. In the meantime physicians must do their best with the tools at hand.

Dr. Osler gives the following suggestions for a plan of campaign against consumption: (1) He would institute an educational health campaign in the homes. (2) In all cities a compulsory notification of cases should be enforced. (3) In most cities the powers of the Health Boards should be greatly enlarged, so as to deal efficiently with the question of proper disinfection of the houses occupied by tuberculous patients. (4) The question of the housing of the poor needs attention, particularly in the matter of proper control of tenements, and the regu-

lation by law of the number of persons in each house. (5) By placing upon the landlord the responsibility of providing, under the control of the Board of Health, a clean, wholesome house for a new tenant, much good may be effected. (6) The wholesale condemnation of unsanitary streets and blocks, and the rebuilding by the municipality, as has been done in Glasgow and elsewhere, is an essential factor. But as has been said before, such changes must of necessity come slowly, and at the present time a large majority of all tuberculous patients must be treated at home. Dr. Osler points out that in the warfare against tuberculosis the man behind the gun is the general practitioner. The battle cannot be won unless he takes an active, aggressive, accurate part. Two facts must be impressed upon him: (1) That early recognition of the disease can come only from better methods of practice and greater attention to the art of diagnosis. (2) The necessity for a more masterful management of early cases. An early and accurate diagnosis is perhaps the most essential feature of a successful crusade against consumption. This matter has been thoroughly threshed out in recent years.

The second point referred to by Dr. Osler is of almost equal importance. Many medical men when they have to do with a case of pulmonary tuberculosis in an early stage, treat solely by drugs. Dr. Osler states plainly that it is his firm conviction that more tuberculosis patients are injured than helped by drugs. "It is not so much that the drugs do harm per se, but that weeks of priceless value are lost in trying to check a cough and quiet a fever in a patient who is allowed to continue his work and is up and about." Home treatment carried out in a rational manner can and will effect much in cases of consumption in the early stage. The author mentions the following as essentials in this home treatment of consumption in the small towns, country places and the suburbs of our large cities: (1) The confidence of the patient, since confidence breeds hope; (2) a masterful management on the part of the doctor; (3) persistence—benefit is usually a matter of months, complete arrest a matter of years, absolute cure a matter of many years; (4) sunshine by day, fresh air night and day; (5) rest while there is fever; (6) breadstuffs and milk, meat and eggs.

There is no doubt that home treatment of consumption, before the disease has gained too strong a hold upon its victim, can be successfully carried out in small towns, country places, and the suburbs of our large cities. There nevertheless still remain the most fruitful sources of dissemination to be dealt with, viz., the crowded parts of large cities. Home treatment may effect some good even under these conditions, but unfortunately it is but a drop in the bucket. Pulmonary tuberculosis will increase and multiply, until the poor of great cities are provided with healthy homes and overcrowding it strictly prohibited. Sanatoriums erected in the country for the treatment of indigent city patients suffering from consumption in its early stage would be a step in the right direction.

The question of extirpating consumption is after all a state and municipal one. Municipalities should provide decent dwellings for the poor, and cities and states should build sanatoriums for the same class. Such a movement would be economical in the long run, for it is the only means whereby consumption can be driven out, and it is needless to insist that the abolition of consumption or even a great lessening in the prevalence of the disease would be an economical measure of the first rank.

ALTERATIONS IN THE HEART FOLLOWING ATTACKS OF ANGINA PECTORIS.

The exact mechanism of the attack of angina pectoris is not clearly understood, although it is believed to be related to the contractility of the heart muscle. The lesions commonly observed after death consist in sclerosis of the coronary arteries, with or without infarction or softening or degeneration of the myocardium. On the other hand, it is not generally appreciated that the attack may be followed by demonstrable changes in the heart. Dr. W. Kernig (*Berliner klinische Wochenschrift,* January 2, 1905) recognizes several groups of cases in which such changes may be observed. These cases are always severe with reference to both the intensity of the pain and the duration of the attack. In the first group a mild febrile state develops in conjunction with demonstrable increase in the area of cardiac percussion—dullness as compared with the size of the heart before the attack. In the absence of other cause of fever, the elevation of temperature may be attributed to softening or inflammation of the myocardium. The second group comprises cases in which, with or without fever, obvious changes in the heart referable to dilatation of one or another cavity make their appearance under the eye of the observer. In the third group are included cases in which acute pericarditis develops in the sequence of an attack of angina pectoris. Although this condition has received but little clinical consideration, it has long been known anatomically. Its occurrence is attributed to the invasion of the pericardium by bacteria from the area of myocardial softening or infarction or abnormal perviousness of the smaller vessels. Mural endocarditis secondary to areas of myomalacia in the sequence of attacks of angina pectoris has likewise been reported. A fourth group of cases may be distinguished in which in the absence of evidence of changes in the heart demonstrable by physical means symptoms of functional derangement make their appearance, such as diminution in the amount of urine and the development of edema. In view of the foregoing facts not alone should patients suffering from angina pectoris be kept under observation for some time after an attack of any considerable degree of severity, but they should also be enjoined to secure complete physical rest in bed for days and even for weeks in order to avert a fatal termination.

Flies and Enteric Fever.

Major A. R. Aldridge, R. A. M. C., writes in the December issue of the *Journal of the Royal Army Medical Corps,* on flies as factors in the spread of typhoid fever. He points out that the disease is markedly more prevalent in those armies in which dry methods of removal of excreta are in use, than in those in which water carriage is employed. Greater prevalence of the disease is to be noted in armies on active service and in countries such as India, where dry methods are universal, and a difference is most apparent in the numerous places in Europe where the two methods are in force side by side.

Major Aldridge thinks that the reason why mounted corps suffer more from enteric fever than dismounted, is that flies are more numerous in the lines of mounted than in those of dismounted corps, owing, no doubt, to stable litter being a favorite breeding place for them.

Burying excreta, according to the writer, does not do away with the danger of dissemination by means of flies, for in Indian cantonments excreta are buried in somewhat shallow trenches and the common house fly breeds therein in enormous numbers. It seems probable that the eggs are laid in the filth in the latrines, and the larvæ hatched out after it has been put into the ground.

From observations made by Major Aldridge, he concluded that treatment of the sewage in a septic tank would lead to the destruction of the eggs or larvæ as they were hatched out, provided it be allowed to remain in the tank from twenty-four to forty-eight hours.

That flies do convey typhoid fever is certainly well proven, and measures should be formulated and carried into effect to prevent the transmission of disease by their agency. In this connection it would be interesting to learn the methods employed by the Japanese Army Medical Department to prevent the dissemination of typhoid fever. In Manchuria during the summer the weather is extremely hot and flies abound, but we heard nothing last summer and autumn of any widespread epidemic of this disease among the Japanese troops.

Spotted Fever.

This disease, which has for many years caused much sickness and a considerable amount of mortality in the Bitter Root Valley of Montana, has been investigated on more than one occasion. The decision arrived at was that it was caused by a pyroplasma, that it was transmitted by ticks, and it originated in spermophiles (popularly known as "gophers"). From the early part of May to the beginning of July, 1904. Dr. Charles Wardell Stiles was engaged in studying the matter from a zoölogical point of view, and has now made a preliminary report, which is published in the Report of the Surgeon-General of the Public Health and Marine Hospital Service.

Dr Stiles has been unable to confirm the former hypothesis as to the origin of the disease. Among the arguments brought forward by this investigator against the tick theory, is that in five of the ten cases seen by him he was unable to establish a history of tick bite. Despite a total of at least one hundred hours' microscopical work on fresh blood, taken at various times night and day from nine cases, he was unable to find any structure which could be interpreted as a protozoon. Certain clinical features of the disease, notably the thickened condition of the blood and the condition of the urine, did not support the view that the disease is due to a pyroplasma.

Dr. Stiles concluded by stating that his work has been negative, so far as cause, treatment, and prevention are concerned, and that with regard to present theories respecting the disease, his results have been entirely of a destructive nature.

New Etiology and Prophylaxis of Appendicitis.

Dr. A. F. A. King of Washington, in a paper read before the Medical Society of the District of Columbia, November 30, 1904, propounded a novel theory as to the prevalence of appendicitis. According to this theory the cause of the frequency of the disease is the bicycle. Dr. King shows that chronologically the appendicitic era began soon after the introduction of the bicycle, and that the disease has increased in a corresponding ratio with the increase of the use of the wheel. With regard to the modus operandi of cycling in producing appendicitis, typhlitis, and perityphlitis, it was pointed out by Dr. Byron Robinson of Chicago in the Medical Record, November 30, 1895—but without any reference to bicycling—that "the psoas muscle may be taken as the standard of reference in regard to the pathological condition of the cecum and appendix"; and again he says, "When favorable pathological conditions arise in the bowel contents, the traumatic action of the motion of the muscle induces microbic invasion through the appendicular wall." Dr. King contends that bicycling brings about such an action of the psoas muscle as to induce the invasion referred to by Dr. Robinson. It is certainly true that appendicitis has been vastly more frequent, or at any rate more generally recognized, since the introduction of the bicycle. The point, however, as to whether the psoas muscle is used in an unnatural manner when bicycling is a moot one. Bicycling has decreased very largely during the past two years, but it does not seem that appendicitis is less common. If, when the bicycle has practically disappeared, appendicitis still holds its own as a popular disease the majority of observers will reach the obvious conclusion that the connection between bicycling and appendicitis is by no means intimate. Apropos of nothing in particular, we may recall the sage observation made by a writer in one of the English medical journals two or three years ago, that the habit of smoking cigarettes and the prevalence of appendicitis had both increased during the past two decades, and consequently it was reasonable to suppose that the former was the direct cause of the latter—or the latter of the former, we forget which.

Salts of Potassium as a Prophylactic for Blackwater Fever.

Dr. Matthew Cameron Blair, writing from West Africa to the *Journal of Tropical Medicine* for September 1, 1904, gives some interesting details with regard to the use of salts of potassium among the natives of that region and of Central Africa. He draws attention to the fact that a prominent article of barter—perhaps the most prominent—along the numerous trade routes which radiate through Central Africa, is native potash. The natives use it largely and habitually, and as they suffer very rarely from blackwater fever, although, in childhood certainly, they are greatly subject to malarial fever, the writer thinks the comparative native immunity to blackwater fever may be due to this habitual dietetic use of salts of potassium. Dr. Cameron explains the immunizing properties of salts of potassium as follows: "Given a sudden escape of free hemoglobin into the liquor sanguinis through destruction of red corpuscles, it is reasonable to suppose that, given a plentiful supply of potassium, this hemoglobin will at once be utilized for the manufacture of new red blood corpuscles; while, in its absence, the free hemoglobin will escape into the urine." Dr. Cameron advises therefore that these salts should be made a constant element in the dietary of Europeans in the fever districts of Africa, especially if they have already suffered from malarial attacks.

Brilliancy Not Desirable in Surgeons.—Sir Frederick Treves in a recent address said that he had come to the conclusion that men of genius were entirely out of place in the medical profession, where even cleverness is not to be encouraged. Indeed, of all desperately dangerous persons the brilliant surgeon is the most lamentable.

News of the Week.

An Extra Pharmacopeia for America.—The Council on Pharmacy and Chemistry of the American Medical Association announces the preparation of a book, to be entitled "New and Nonofficial Remedies," to contain a description and indication for the employment of the various synthetic and proprietary remedies sold under a trademarked name. Only such drugs and preparations as conform to the following ten rules will be admitted to this semi-official formulary. (1) No article will be admitted unless its active medicinal ingredients and the amounts of such ingredients in a given quantity of the article, be furnished for publication. (2) No chemical compound will be admitted unless information be furnished regarding tests for identity, purity, and strength, and if a synthetic compound, the rational formula. (3) No article that is advertised to the public will be admitted; but this rule will not apply to disinfectants, cosmetics, foods, and mineral waters, except when advertised in an objectionable manner. (4) No article will be admitted whose label, package, or circular accompanying the package, contains the names of diseases, in the treatment of which the article is indicated. The therapeutic indications, properties and doses may be stated. This rule does not apply to vaccines and antitoxins nor to advertising in medical journals, nor to literature distributed solely to physicians. (5) No article will be admitted or retained about which the manufacturer, or his agents, make false or misleading statements regarding the country of origin, raw material from which made, method of collection or preparation. (6) No article will be admitted or retained about whose therapeutic value the manufacturer, or his agents, make unwarranted, exaggerated or misleading statements. (7) Labels on articles containing "heroic" or "poisonous" substances should show the amounts of each of such ingredients in a given quantity of the product. (8) Every article should have a name or title indicative of its chemical composition or pharmaceutic character, in addition to its trade name, when such trade name is not sufficiently descriptive. (9) If the name of an article is registered, or the label copyrighted, the date of registration should be furnished the council. (10) If the article is patented—either process or product—the number and date of such patent or patents should be furnished. If patented in other countries, the name of each country in which patent is held should be supplied, together with the name under which the article is there registered.

A Meningitis Commission.—At a recent meeting of the Health Department of this city, Dr. Darlington was empowered to ask the Board of Estimate and Apportionment for a small sum to pay a commission to investigate the unusual prevalence of cerebrospinal meningitis, and try to find some remedy, to retard, or, if possible, stamp out the disease. In January, 1904, there were twenty-five deaths, while in the same month this year there were 107. In February, 1904, there were twenty-six deaths, while in February, 1905, there were 149.

Yellow Fever on the Isthmus.—In a recent communication to the Panama Canal Commission, Gen. Davis, Governor of the Canal Zone, says concerning the prevalence of yellow fever: "Thirty-three cases of recognized yellow fever have been found on the Isthmus of Panama since last May, and of this number nine terminated fatally. There is one man in the hospital to-day seriously ill from yellow fever; six have recovered. Three new cases have been reported since Feb. 1. The whole city of Panama—and it is only in Panama that the infection exists—is being thoroughly disinfected. Of canal employees and their families coming here from the United States, only four out of some 400 or 500 have been sick from yellow fever, and of this number, one case terminated fatally."

The Status of Christian Science in Ohio.—A decision of the Ohio Supreme Court holds that Christian Science healers cannot practice without a State license. The court says: "The giving of Christian Science treatment for a fee, for the cure of disease, is practicing medicine within the meaning of the statutes regulating such practice in this State. The statute making it a misdemeanor to give such treatment for a fee is not interference with the rights of conscience and of worship, and is not on that ground unconstitutional. Legislation prohibiting any one from treating a disease for a fee, excepting such persons as have prescribed qualifications, is a valid exercise of the police power of the State and is constitutional."

The American Laryngological, Rhinological, and Otological Society.—The Eleventh Annual Meeting of the American Laryngological, Rhinological, and Otological Society will be held under the Presidency of Dr. Frederic C. Cobb, at Boston, Mass., on Monday, Tuesday, and Wednesday, June 5, 6, and 7, 1905. The secretary is Dr. Wendell C. Phillips, 40 West 47th Street, New York.

The Society of Medical Jurisprudence.—At the meeting of this society, to be held on March 13, Dr. Ferd. C. Valentine will read a paper on "Some Forensic Problems Regarding Venereal Diseases." Among those who will address the paper are Drs. Prince A. Morrow, Frederick R. Sturgis, Emmet C. Dent, and A. H. Goelet.

A School of Philanthropy at Columbia.—At a meeting of the Trustees of Columbia University on Monday of this week, it was announced that Jacob H. Schiff had given $100,000 for the endowment of a Chair of Social Work. The new professorship was filled by the appointment of Dr. Edward T. Devine, General Secretary of the Charity Organization Society, Director of the School of Philanthropy, and Editor of *Charities*. This endowment makes possible the close affiliation between the School of Philanthropy and Columbia University.

The Columbus Hospital, Chicago, was formally thrown open February 26, under the cabled blessing of Pope Pius X, and the spoken benediction of Archbishop Quigley. In the afternoon, dedication exercises were held by the prelate and prominent laymen. The new hospital was founded and will be conducted by the Missionary Sisters of the Sacred Heart. Its equipment is complete and modern, and $200,000 was spent in building and fixtures. The hospital will be conducted on non-sectarian lines. Dr. John B. Murphy, President of the Medical Staff of the Hospital, made the first address of the afternoon, and was followed by Judge Brentano, S. S. Gregory, and others. The hospital is of stone and steel, six stories high, with 85 rooms and 4 large wards with 300 beds. It has rooms for operations, sterilizing, antiseptics, pathological, microscopical, and *x*-ray work.

A Medical Library has been established by the Atlantic City Academy of Medicine, and this Society has entered into an arrangement with the Atlantic City Free Public Library by which a room has been set apart for its books and periodicals. To physicians visiting Atlantic City will be extended every courtesy the library can offer. Contributions on medical subjects will be gladly received, and may be directed to Dr. Wm. Edgar Darnall, President of the Acad-

emy, or Dr. Philip Marvel, Chairman of the Committee.

Phipps' Dispensary Opened.—The dedication of the new tuberculosis dispensary at the Johns Hopkins Hospital, took place on February 21, in the presence of the founder, Mr. Henry Phipps of Pittsburg, Pa., and from 300 to 400 other persons. Dr. H. M. Biggs, of the health department of this city, delivered an address on "The Advantages of a Tuberculosis Dispensary"; Dr. H. Barton Jacobs, president of the Laennec Society of Baltimore, spoke on "The Origin and Rise of Tuberculosis Dispensaries," while Dr. William Osler, of the Johns Hopkins Hospital, made an address on "Tuberculosis in the General Hospital." Mr. Phipps originally donated $20,000 for the establishment of the dispensary, and now has added a further sum of $5,000 to this amount, to assist in carrying on the work. The dispensary is a branch of the Henry Phipps Institute for the Study, Treatment and Prevention of Tuberculosis, which was established in Philadelphia in 1903, although it will be under the direct management of the Johns Hopkins Hospital authorities.

Association of American Medical Colleges.—The next meeting of this association will be held in Chicago on Monday, April 10, 1905, under the presidency of Dr. Samuel C. James. The secretary is Dr. Fred C. Zapffe, 1764 Lexington Street, Chicago.

The Phipps Model Tenements.—Two sites have been acquired upon which model tenements will be built with the fund of $1,000,000 provided for that purpose by Henry Phipps. One of these sites consists of seven lots on the north side of Thirty-first street, just east of Second avenue, upon which there are now old tenements. The other covers sixteen lots on Sixty-third and Sixty-fourth streets, eight lots on each street, beginning about 150 feet east of West End avenue. On the latter site houses exclusively for negro tenants will be built. Plans for the new tenements have not been sufficiently advanced to admit of any detailed description. It is understood, however, that the buildings will be six stories in height, each one occupying a plot 40 by 100 feet. All other model tenements will be carefuly studied, and all of their best features embodied in the Phipps houses.

Bactericidal Money.—In support of a bill for clean paper money, which was under consideration by a committee of Congress just before the dissolution of that body, Dr. Darlington, Health Commissioner of New York, presented a report of some studies made by Dr. Wm. H. Park to ascertain the influence of coin and of paper money upon the life of diphtheria bacilli. The experiment was made of placing pennies, nickels and dimes in the mouths of children suffering from diphtheria. The coins showed no traces of diphtheria bacilli twenty-four hours afterward. The report thus sums up the results reached: Pennies at the end of twenty-four hours gave a growth of diphtheria bacilli when fairly dry bacilli were placed on them, but none when placed on wet. Pennies at the end of forty-eight hours gave no growth. Nickels at the end of twenty-four hours gave a growth at times, but not at others. Nickels at the end of forty-eight hours gave no growth. Dimes at the end of twenty-four hours gave a growth at times and not at others Dimes at the end of forty-eight hours gave no growth. Paper money at the end of forty-eight hours gave a growth and continued to do so at times up to one month. The results of these experiments indicate that the metallic substances in coins when brought in contact with bacteria through the solvent action of moistures are deleterious, while in paper there are no such substances, the gradual death of bacteria being due to the effect of drying.

Sanitary Improvements in the New York Post Office.—The Committee on the Prevention of Tuberculosis of the Charity Organization Society, has called the attention of the Washington authorities to many unsanitary conditions existing in the post-office building, and the necessary alterations will, it is said, be made at once.

Opposed to Baby Incubator Shows.—A bill has been introduced in the New York Legislature making it a misdemeanor to exhibit in public any infants in incubators. The bill was drawn up by the Society for the Prevention of Cruelty to Children.

Sanitary Treaty Ratified.—On March 1, the U. S. Senate ratified and made public an international sanitary treaty, adopted by a convention of representatives of practically all nations, held for the purpose of agreeing upon uniform safeguards of the public health against the invasion and propagation of plague and cholera.

Illinois Sanatorium for Consumptives.—There is a good prospect of the passage of Mr. Glackin's bill appropriating $200,000 for the erection of a sanatorium for consumptives in Illinois. The enactment of this bill into law will provide the State with an institution, which will overshadow any other institution in importance. A large number of prominent citizens have endorsed the bill.

A Testimonial to Dr. Murrell.—The sum of £1,000 has been presented by Mr. Edward Heron-Allen to the Westminster Hospital, London, to endow a bed in one of Dr. Murrell's wards "in recognition of his valuable contributions to pharmacology and his researches on the action of remedial agents in the treatment of disease."

Patent Medicines in Danger.—It appears that the makers of proprietary remedies sold in Cuba, have only narrowly escaped the necessity of publishing the formula of their nostrums. Deaths of several ignorant people, traceable to overdoses of certain patent medicine, caused the Cuban government to resurrect an old Spanish law requiring that the formula of every patent medicine be printed upon the label of the bottle in which it is sold. Manufacturers of American medicines at once foresaw loss of the secrecy heretofore protecting their products, and used their influence to have the Cuban government modify its stand. It was finally agreed that the revised law should operate simply to the extent that patent medicine formula should be filed with the Cuban government, and by it be kept secret. If the formula shows any medicine to be dangerous, proper restrictions will be placed around its sale.

Recognition of Christian Scientists.—The Christian Scientists are again attempting to obtain recognition under the medical laws of the State. Two bills have been introduced before the legislature, providing that when the Regents of the State University prepare examination papers for applicants to medical practice they shall prepare questions on "mental science as a means of promoting and preserving health," and that in the preparation of rules for examination of nurses, these rules shall provide, "among other things, for an examination in mental science as a means of promoting and preserving health."

More Cases of Wood Alcohol Poisoning.—The whiskey provided for the mourners at an East Side funeral last week appears to have been quite as vile a concoction as any sold in the infamous Striker's Farm district, a short time ago. One man is dead, another is totally blind, and several others are or have been sick, as the result of drinking the mixture, the low price of which was accounted for by the supposition that it was moonshine whiskey.

Dr. Stella Stevens Bradford has been appointed medical school inspector by the Montclair Board of Health.

Adulteration of Candy.—A report to State Commissioner of Agriculture Charles A. Wieting, by Dr. Joseph F. Geisler and Professor E. G. Love, shows that the cheaper candy sold in the city, is adulterated to a surprising degree. In more than two hundred samples taken from New York stores and submitted for analysis, paraffin was found in caramels, chocolates, and molasses candy; ordinary varnish was discovered as a coating for chocolates; aniline red and blue were detected as a coloring in gum drops and sticks of candy, while glucose was found in nearly all the cheap confections. The report included analyses of maple sugar, jellies, catsup, and honey. Of sixty-nine catsups, all but one showed added color, a sample of maple sugar contained at least ninety per cent. of cane sugar, and the honey examined was largely adulterated with cane sugar or glucose.

Patients Give Hospital $10,000.—Grateful because of their quick recovery, two private patients in the Roosevelt Hospital have given the institution $5,000 each for the opening of one of the public medical wards, which has been closed for some time owing to the lack of funds.

A New Property of Radium.—Professor Chaveau announced in a recent communication to the Parisian Académie des Sciences that, radium emanations have the property of destroying the toxicity of serpent venom. Viper and cobra poison, if submitted to the action of radium, is said to lose its virulence after fifty or sixty hours of exposure.

A Source of Dissecting-Room Material.—According to an Indiana newspaper, the removal of an axe factory has cut down very largely the supply of anatomical material of Indianapolis medical colleges. The workers in the factory were largely negroes, among whom pulmonary diseases, due to work at the grinding machines, were very common. Nearly all had insurance policies which, before death, were usually assigned to some friend for the purpose of paying the funeral expenses. The money was usually converted to other uses, however, and the body allowed to go to the destination the law prescribes for paupers. The removal of the factory resulted in a prompt decrease of available cadavers.

The National Fraternal Sanatorium for Consumptives.—A movement is on foot among the labor unions of the country, to organize a large tuberculosis camp or colony in New Mexico, where members of the unions and their families may receive suitable climatic and medical treatment at little or no personal cost. The Temple of Fraternity, a $90,000 building erected for the St. Louis exposition, by the World's Fair Fraternal Building Association, has been presented to the National Fraternal Sanatorium, and will be wrecked, transported to the site chosen, and then rebuilt, to serve as the administration building for the colony. The heads of the cigar makers' unions are also endeavoring to establish sanatoria for consumptives in various appropriate sections of the country.

Lower Death Rate.—The Health Commission reports that the death rate in this city for the week ending March 4 was lower than that for the corresponding week in any previous year. It was 20.47 per thousand, while for the corresponding week in 1904 it was 24.35, and in 1903, 20.67. There were fewer deaths from all causes over the same week last year, except from cerebrospinal meningitis. There were forty-nine deaths from that cause. Lobar pneumonia caused seventy-eight fatalities during the week, while during the same time last year there were 201.

Disease Invades the City of Healers.—Several of the prominent officers of Zion City have recently suffered severe illness, and some have died, and now it is said that Dowie himself has cancer which he cannot cure or get cured by the extra-surgical methods of his list.

Obituary Notes.—Dr. James Taylor Pirtle, of St. Louis died at his home in that city on February 27, Dr. Pirtle was 69 years of age and had practiced in St. Louis for two score years, being one of the oldest practitioners in the city. He was graduated from the St. Louis Medical College (Medical Department Washington University), in 1864.

Dr. James Paxton Barclay of Eutaw, Alabama, died February 17, at the age of 57 years. He was a graduate of the New York University Medical School in the class of 1871.

Dr. W. E. Bessey of Grand Rapids, Mich., died February 15, at the age of 80 years. He was born in Canada and was graduated in medicine from McGill University.

Dr. William Edward Griffiths died at his home in Brooklyn, on February 27, at the age of 63 years. Before his graduation from the College of Physicians and Surgeons of New York in 1868, Dr. Griffiths served for two years as surgeon's steward on the United States frigate *Colorado* in the civil war. He was visiting surgeon and consulting physician of St. Mary's Hospital and a member of the Kings County Medical Society. He served for fourteen years in the Brooklyn health department as a sanitary inspector and chief inspector of contagious diseases.

Dr. Adolph Ziperlin, an honorary member of the Faculty of the University of Tübingen, Germany, from which university he was graduated in 1840, died at his home, in Cincinnati on February 28, aged nearly ninety years. He was a surgeon in the Union Army during the civil war.

Dr. L. C. Bean of Waukegan, Ill., died February 22, of pneumonia, at the age of 84 years. He was born in New Hampshire and was graduated from the Vermont Medical School in 1849.

Dr. Milton E. Hammer of Baltimore died February 24, at the age of 39 years. He was a graduate of the University of Maryland Medical School in the class of 1890.

Dr. George D. Boon of Chetopa, Kan., died February 21. He was a graduate of the Medical Department of the University of Michigan in 1870.

Dr. John Jay Prendergast died March 1, at his home in Brooklyn, at the age of 62 years. He was one of the founders of the Manhattan Eye and Ear Hospital, and was also, at one time, a member of the visiting staff of St. Francis' Hospital, Jersey City. He was a graduate of the College of Physicians and Surgeons in this city, in the class of 1868.

Dr. Wm. B. E. Miller formerly of Camden, N. J., died at Hightstown, N. J., on March 2, at the age of 56 years. He served in the Federal army during the civil war, was for a number of years Federal Inspector of Cattle at Jersey City, and served for two terms as a member, and for one term as president of the Camden City Council.

Dr. C. W. Crowell of Marshall, Tex., died February 22 from pneumonia. He was a graduate of the Chattanooga Medical College.

Dr. Walter S. Christopher of Chicago died of heart failure March 2, at his residence. He had been ill since last August. He was 46 years old, and was born in Newport, Ky., in 1859. He was graduated from the Medical College of Ohio in 1883. During the last year of his course in the college he was an interne at the Cincinnati Hospital. As a student Dr.

Christopher had been interested in children's diseases, and upon his graduation he was made assistant in the children's clinic of the Medical College of Ohio. In this capacity he served seven years. In 1884 he became demonstrator of chemistry and continued in this relation until 1890. In 1890 he was called to the Chair of the Theory and Practice of Medicine in the University of Michigan. After a year's service in that institution he went to Chicago in 1891, and was appointed Professor of Diseases of Children at the Chicago Policlinic. A similar appointment to the College of Physicians and Surgeons of Chicago was made in 1892. He was an ex-president of the American Pediatric Society.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HUNTER'S DAY—A BLUE BOOK ON CANCER—PANCREATIC SECRETION—MILK SUPPLY—TYPHOID AT LINCOLN—CHARING CROSS HOSPITAL—GIANTS—HOME OF RECOVERY—OBITUARY NOTES.

LONDON, February 17, 1905.

HUNTER'S day is a great day at the Royal College of Surgeons, the home of this great museum. John Hunter was born on the 13th or 14th of February, 1728. There is a little uncertainty, but we keep the 14th as his day. This year the oration was delivered by Mr. John Tweedy, President, and a distinguished company gathered at the College to hear it. Having sketched Hunter's career and referred to the state of medical knowledge in his day, when he and his brother introduced systematic anatomical teaching, the President asked, What did Hunter do? and answered, he made one of the largest collections of biological specimens, the great museum now lodged in the college; but, said the orator, however precious the museum, it represented only the material part of his work. The impulse he gave to the operation of mind in the pursuit of biological knowledge was infinitely greater and would last while civilization endures. Amid the multiplicity of apparently conflicting phenomenon, he discovered unity. He had a large knowledge of facts, a fertile imagination ready to suggest the relations between them, but he submitted every hypothesis to the tests of observation and experiment. Some of his discoveries might be called accidental, but such accidents happen only to those who deserve them. The greatest men are estimated by their influence on the thoughts and activities of those who follow them; so judged Hunter is among the greatest. There are persons who would not hesitate, in the sacred name of religion, to traduce the memory of Hunter because he practised experiments on animals, though all through historic time man has continued to capture, subjugate, and slay beast, bird, and fish for his pleasure, his sustenance, and his service. Is lordship over animals given to man only for the satisfaction of his physical and sensuous needs? Is not life more than food? Does mind need no aliment? Is a veto to be applied only when the purpose is to elucidate the kindly functions of physiology or the baneful secrets of disease? In anticipation of the Great Passover, Moses commanded the Israelites to sprinkle their lintels with blood. Who shall say that the Angel of Death in our day, seeing the immunizing blood, may not take it for a token not to come into our houses? And so we may enjoy a growing freedom from pestilence, and in the fulness of knowledge and time the measure of our freedom may become full.

In the evening the dinner was held in the college, Mr. Tweedy presiding. The loyal toasts, the army and navy, were duly honored, and the "memory of John Hunter" drunk in silence.

Two years ago Mr. Chamberlain issued from the colonial office a circular to the authorities of all British Colonies and Protectorates, calling attention to the formation of the cancer research fund, and directing everything to be done to obtain information and specimens. The result is a blue-book issued this week. The first replies were largely of a negative character, *e.g.* Mr. Samuelson in Natal, though intimately acquainted with native life, had never known of a case of cancer among the natives, and from Gambia a similar report was made. At the request of the Cancer Commission a further circular was issued, suggesting that perhaps the apparent absence of cancer in some populous colonies might be due to hospital patients being usually under the cancer age. This brought many replies. From these it would really seem that cancer is rare in some races, though from what causes is by no means clear. It is suggested that few aboriginal men or women exceed the age of forty-five, below which the disease is rare in civilized peoples. This hypothesis seems to rest on rather slender evidence. The committee recognize this and express a wish that the ages of any natives who may suffer from cancer may be ascertained, and, further, that the average age attained by native men and women may be investigated.

Here are some of the facts reported. In the Gibraltar Hospital five deaths from cancer in 1903. In the native (Spanish) population the surgeon attributed the predisposing causes to excessive cigarette smoking in males, and early maternity in females. Possibly deep seated cases were not diagnosed and autopsies are with difficulty obtained. From British Honduras and from Sierra Leone, we are told that cancer does occur at times, but is rare and, therefore, opportunity for observation is slight. The commissioner for British Central Africa thinks that cancer, though it does exist, is rare within his jurisdiction, and he quotes two medical men with great experience among the natives who, between them, have met with only two certain cases and one doubtful one. There is a disinclination to apply for aid if surgical operations are likely to be recommended. From Wei-hai-wei it is said cases are rare, and the Chinese refuse to admit post-mortem examinations. In the East African Protectorate the doctors say cancer is rare among native tribes, but the medical missionaries in Uganda have met with cases. In Mauritius, hospital returns give fewer cases than in England, but it is admitted that little is known as to the occurrence of cancer in the mixed population. In the Transvaal it is reported that the disease is practically confined to Europeans. In Ceylon the deaths are said to be one in 450 per annum.

A third circular was sent out last November, urging the importance of forwarding specimens for miscroscopical examination, when there are not facilities for carrying out such on the spot.

Some interesting observations on the pancreatic secretion in man were communicated to the Pathological Society in the course of a paper by Dr. Clayton-Greene. After a pylorectomy in which the pancreas had been torn and ligatured a pancreatic fistula formed and the effect of food on the secretion was observed. A few seconds after beef tea, etc., was swallowed, a definite secretion of pancreatic juice took place. The sight of food had the same effect, just as when the salivary glands are stimulated. These facts were noted for 10 days, when the patient became worse and died. At the autopsy the pancreas was in a state of general suppuration, but there was no fatty necrosis. The observations support Pawlow's view that pancreatic secretion is influenced by a nervous mechanism, and suggest that the secretion may be started by stimulation of a sensory nerve, although secretin or prosecretin may be concerned in its maintenance as shown by Starling and Bayliss.

The milk supply of towns is a subject which bristles with difficulties, even to the most zealous sanitary reformers. Dr. McClery last week read a paper before the Incorporated Society of Medical Officers of Health, in which he advocated the municipalization of the supply as the only remedy for the abuses which prevail. This he argued would secure a fixing of responsibilities, cheapening of production and distribution, freedom from adulteration, and other benefits. This view is, I am aware, held by some eminent authorities, but the majority are against it. Dr. Boobyer criticised it from a financial point of view, and said the public was strongly opposed to the increase of municipal expenditure. Mr. Sadler, of the Cheshire Milk Supply Association, said that in his county alone there were 100,000 cows worth £20 each. These and the farms and dairy plants would have to be bought. They should improve present methods instead of trying to end them; sterilize the milk in cooperative depôts, look after the condition of the railway vans, and economize the cost of distribution.

Lincoln is suffering from a widespread epidemic of typhoid fever of a mild type. Over 600 cases are reported. A medical inspector has been sent down by the Local Government Board, and in due time we may learn much about the outbreak. Meantime, it may be stated that the sanitary authorities of the city have incurred a heavy responsibility by their neglect of obvious precautions, and more than that, by their refusal to remove dangers which were pointed out to them years ago. It really sometimes looks as if local government was a failure. In some places, as in Lincoln, the local bodies will not listen to expert advice or expend money on precaution. In others they seem never at rest, and pile up debts in the most reckless fashion. So that the municipal indebtedness of the country is becoming a danger in the eyes of financial experts.

At Charing Cross Hospital, the annual meeting of governors on Wednesday was the occasion of congratulations on the completion of the renovation and extension. Lord Burnham, who presided, said he could not doubt that the improvement would have its reward in increased contribu-

tions. £23,000 is still required—enough to show that the managers, like so many others, did not fear to run into debt. In replying to a vote of thanks, Lord Burnham announced that his two sisters, Miss Matilda Levy and Lady Campbell Clarke, would give £3,000 and £1,000 respectively, to complete the Levy ward named after his family.

We have another giant on exhibition in London. I have not seen him. Some of those previously exhibited were evidently cases of acromegaly. Not so the Irish giant whose skeleton is in the Hunterian Museum. The current number of *Blackwood's Magazine*, has a timely article by Miss Masson, on John Hunter's wife, in which she tells again the story of how the corpse of the giant was secured for Hunter.

Last evening the Duke of Portland presided at a dinner in aid of a "Home of Recovery," which it is intended to build in Surrey, for patients discharged from surgical wards of the London hospitals, who are not well enough to resume their work. £30,000 is required to endow the home; it is intended to raise the money before proceeding. Sir F. Treves supported the movement, and said no scheme appealed more to hospital surgeons. A sum of £1,335 has been raised towards the amount required.

Last month I noted the deaths of some aged doctors from 80 to 90 years of age. Another, still older, has now passed over, almost a centenarian, Dr. Nathaniel Davidson, born in March, 1805, L.R.C.S. Ed., in 1828. He practised for many years in London, but long since retired to the country. He died in the Isle of Wight on the 9th inst., and was buried there on the 14th inst.

Dr. Robson Roose died on the 12th inst., aged 56. He qualified in 1870. He enjoyed, for a number of years, an extensive practice among the fashionable set. He was a genial host, much given to hospitality and his dinner table was often graced by distinguished statesmen, artists, and all sorts of notabilities, not omitting those of his own profession.

OUR VIENNA LETTER.

(From Our Special Correspondent.)

A NEW STATION FOR FREE MILK DISTRIBUTION—THE TECHNIC OF DIAGNOSIS—A NEW DIAGNOSTIC SIGN IN ECTOPIC GESTATION—SYPHILIS IN ANIMALS—ABSORPTION OF ALBUMINS—TREATMENT OF LARYNGEAL TUBERCULOSIS BY DIRECT SUNLIGHT.

VIENNA, February 25, 1905.

Vienna has, during the last few days, come into the possession of an institute for the purpose of combatting mortality among infants. A small building has been erected in connection with the St. Anna's Pediatric Hospital which, according to Professor Escherich's inaugural address, is intended to accomplish the following objects: In the first place, women of the poorer classes, who inquire, are to be given instruction in the care of their children. A physician is to be in daily attendance for the purpose of answering questions, and printed information slips will be distributed. As far as means will allow, the needy will also be given material assistance, and a committee of ladies is engaged in collecting clothing and utensils of all sorts for the protegées, who will also be visited in their homes, for the purpose of rendering all possible aid. Secondly, wholesome, properly prepared milk is to be distributed gratuitously to deserving mothers of infants. Five thousand children are born in Vienna every year, but one thousand of the number die before reaching the end of the first year, and four-fifths of the deaths are due to digestive disturbances in bottle-fed infants, due to improper nature and preparation of cow's milk. Escherich believes that the establishment of this institution represents the most satisfactory solution of the problem at present feasible. In passing, it may be said that humanitarian associations give away infants' milk to poor mothers in two other districts of the city, and it is the intention to found other establishments for this purpose. The present building contains a waiting room, an office, a bathing room for infants, a sterilizing room, the milk distributing room, a medical examining room and kitchen for milk, a bottle washing room and a laboratory.

Professor Nothnagel recently delivered an address on "The Technic of Diagnosis," in the course of which he said that it is neither the physical aids, nor the results of chemical or microscopical examination which enable physicians to arrive at a diagnosis. Diagnosis is at once an art and a science, and the scientific element should predominate, so that the more thoroughly a physician is imbued with the scientific spirit, the better a diagnostician he will be. Still, it is true that there are physicians of such temperament that diagnosis comes to them like a sort of poetical inspiration, and they are gifted with the faculty of intuitively grasping the connection of a series of manifestations; in other words, they possess a certain amount of what is called genius. The celebrated Oppolzer was more of an artist than a scientist in making diagnoses, whereas Skoda subjected the indications to analysis, and then constructed his diagnosis on this basis. The internists are in the least satisfactory position, for they are often forced to satisfy themselves merely with conclusions. Formerly, in making a diagnosis only the subjective and objective symptoms were considered, but since the work of Rokitansky and Virchow, the conviction has become established that only the anatomical diagnosis, which in some cases may be susceptible of proof on the autopsy table, should form the basis of diagnostics. Should a different point of view be adopted, the result would be a serious calamity for medicine. Of course, the etiology of disease also requires recognition, but this is the weak point in our medical knowledge, for the causes of disease are to a large extent still unknown. This ignorance also weakens our attempts at prophylaxis, by means of which we do, and should, strive to make the physician unnecessary.

At a meeting of the Physicians' Society, Mandl spoke on the clinical significance of milk secretion during pregnancy. Together with Professor Kreidl, he carried on experiments in Exner's physiological institute. Pregnant animals in various stages of gestation were laparotomized and the fetuses killed. The uterus was replaced and the wound closed. Two to four days afterward it was possible to express milk from the breasts, showing that death of the fetus brings about the appearance of milk in the mammary glands. This fact may be used to serve as an aid to diagnosis in extrauterine pregnancy, and Mandl was able to demonstrate it in three cases of tubal gestation. In the first case there was moderate bleeding, with occasional colicky pains in the left lower abdomen, and milk could be expressed from the breasts. On operation a typical tubal abortion was found. In the second case also, in which there was slight but continuous flowing, microscopic examination of the mammary secretion showed the presence of milk droplets, and on operation a tubal mole was revealed. The third case was one in which colicky pains and metrorrhagia accompanied a doughy, sausage-like tumor, situated to one side of the slightly enlarged uterus. Milk could be expressed from the breasts, and on the strength of the diagnosis of a dead ovum in the tube expectant treatment was advised. After several days the mass had almost entirely disappeared, and it was assumed that the ovum had been expelled into the peritoneal cavity and been absorbed. The period was estimated as about the tenth to the twelfth week, so that evidently even in the early weeks death of the fetus is followed by the appearance of milk in the breasts. The detection of this symptom is important, since, according to Werth, every intact etopic gestation should be operated on, in order to guard against rupture and hemorrhage, but if the ovum is dead, expectant treatment may be followed with safety. Expulsion of the decidua from the uterus is not a sure sign of death of the fetus, and the new symptom is, therefore, a welcome addition to our resources. Gessner once reported in a case of tubal pregnancy, operated in the third month, the appearance of milk five days later, and called attention to this sign of death of the fetus, but no attention was paid to his communication, and Mandl desires to emphasize the importance of this fact, which has great value from the standpoint of treatment.

R. Krauss demonstrated to the same society several monkeys that had been inoculated with syphilis. Successful experiments of this nature were first made by Metschnikoff and Roux, in 1903. The anthropoid apes first show an indurated sore, resembling the human chancre, after which an exanthem develops. In the lower monkeys the induration does not break down, and no rash appears. Both varieties are rendered immune to subsequent infection by a single inoculation. The syphilitic virus appears to undergo attenuation by passage through the lower monkeys, but produces typical chancres on reinoculation into the higher apes, although the sore differs somewhat from that produced by human virus.

E. Freund has presented a paper on the first changes in absorbed albumins, based on animal experiments and on the study of freshly removed organs. Töpfer has already reported from these experiments that the liver is able to break down albumin only with the assistance of the intestinal tract. Further observations showed that albumin taken by the mouth is in the intestine split into albumoses and pepton; these products are again synthesized by the intestinal wall and brought to the liver through the portal vein, after which the final decomposition into albumoses, peptons, and urea follows. Further changes in the products depend on the functional nature of the body cells. In hibernating animals the transudation of albuminous bodies into the intestine is reduced to a minimum through reduction in the circulation of the intestinal vessels, in inflammatory conditions metabolism is upset by the more active decomposition of albumins attending the congestion of the bowels.

In Professor Schrötter's clinic the treatment of laryngeal

tuberculosis by means of direct sunlight is being made the subject of extensive trial. The results have been so favorable that it is hardly possible to doubt the value of the method. The time of exposure has varied from six to forty-four hours, and, with one exception, all the patients were greatly benefited. The plan is very simple. The patient sits with his back to the sun and reflects the light into his mouth with an ordinary hand mirror. The fact that the patients can, after a little practice, convince themselves of the progress they are making by observing the image in a laryngeal mirror renders the procedure especially comforting and satisfactory to them.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 2, 1905.

Certain Aspects of Bile Duct Disease.—J. G. Mumford says that the two immediate questions in a case of bile duct disease are, first, shall we operate, and, second, if so, how? In regard to the first question, he says that a faulty digestion may be the initial symptom. Patients are apt to have a small and quickly appeased appetite, with a tendency to corpulence. With this there is a defective metabolism, as shown by constipation, occasional distress after food, indefinite but sharp occasional pains in the upper part of the abdomen, bad taste, furred tongue, frequent headaches, lack of vigor, frequent blurring vision and dizzy spells; in short, the symptom complex that the laity style biliousness. In dealing with such patients we must not forget that there may already be an infected condition of the biliary passages. For many of these Carlsbad salts, regulated life, restricted diet, exercise, massage, etc., will suffice. If, however, in spite of these measures, the patient does not improve, and is seized with gall-stone colic, recourse must be had to surgery. In the choice of a procedure, there are three ends to be attained or principles to be followed. These are thus summarized by the author: (1) Removes stones; for if left behind they are very sure to cause subsequent disturbance, and we know conversely that after the thorough removal of stones, their recurrence is almost unknown. (2) Remove, so far as possible, all disorganized, degenerated and permanently crippled tissue, for such tissue, when left behind, may become the nidus for subsequent inflammation, stone formation, and a return to the invalid condition. (3) Drain, for without drainage we have no certainty of the removal of infectious material.

New York Medical Journal, March 4, 1905.

Retarded Development of Speech in Young Children.—G. Hudson-Makuen gives the details of one case and presents the following conclusions on the general subject: (1) Retarded development of speech in young children may be the result of structural irregularities in the peripheral organs, impaired respiration due to nasal, postnasal, and phayrngeal obstructions, paresis of the nerves supplying the organs of speech, and not infrequently to some disturbance of hearing not necessarily amounting to absolute deafness. (2) Retarded development of speech always results in defective mentality. (3) The treatment consists in the removal of any obstruction that may exist in the peripheral organs and in the systematic training of the auditory and speech centers by the use of specially prepared vocal exercises. (4) A child may be taught to hear in exactly the same way as he is taught to read and write.

Active and Passive Exercise in the Treatment of Syphilis.—N. T. Beers notes that patients suffering from syphilis and actively exercising or leading an outdoor life, do much better under treatment than those who follow sedentary occupations or are shut in. He reminds us that mercury and iodine, the sheet anchors in this dyscrasia are active irritants to the human body. Free exercise is therefore necessary in order to secure proper eliminative activity. If outdoor exercise is impossible, the next best thing is cold bathing, followed by vigorous skin friction and massage. Active athletic exercise therefore is in the syphilitic patient to be encouraged. As to the administration of mercury, the author believes inunction to be the most efficacious method. The patient is allowed to bathe before each inunction if he so desires. Going over the section to be anointed with a little ether, just before applying the ointment, greatly facilitates its absorption. Beers prefers an ointment composed of very pure oil of sweet almonds, wax, gelatin, soap, and water, containing 50 per cent. of mercury. This preparation contains none of the greasy elements which make the use of the old official "blue ointment," so objectionable to many. It has no odor, keeps well, and its application is accomplished with a few moments of rubbing. On the hands, feet, and face the white mercurial ointment is used, preferably before retiring, when required in the first weeks of the secondaries.

Reports of Two Cases of Cured Graves' Disease.—The patients of G. B. Webb were two women, aged respectively, forty-five and forty years. Both had been hard domestic workers and had suffered from great restlessness and severe nervous headaches, in addition to the classical symptoms of the disease. In one case, the patient seemed to have lost the power of guiding her voluntary nerves, but was greatly benefited by being made to realize that her main trouble was a lack of mental control. She was instructed to memorize simple poems, and every day at certain hours to recite these poems to herself and to concentrate her whole being in them. Under such regulated efforts at self-control, her condition greatly improved. In the other case piano playing and horseback riding effected a similar good result. The author therefore reasons that Graves' disease often appears on a distinctly neurasthenic basis and that the relief of the latter condition will often lead to a disappearance of the symptoms of the former malady.

Medical News, March 4, 1905.

The Equilibrium Between Infection and Immunity as Illustrated in the Tonsillar Crypt.—J. Wright considers this question of infection and immunity, dwelling on the various peculiarities of the tonsillar structures, which keep the subepithelial tissues free from the germs which swarm in the crypts. What the exact factor is he does not attempt to decide. He has suggested that there is some sensitive mechanical arrangement which closes the stomata and interstices of cells to the ingress of bacteria, but allows inorganic particles to go through. Or there may be some bacteriolysin which has a selective action against the microbic invasion. Life is a constant warfare between constructive and destructive forces, and some unknown factor controls the equilibrium between the two. The disturbance of this equilibrium may be a freshly virulent organism or an auxiliary organism. The tendency of modern investigators is that the change is usually one of the intrinsic, rather than of the extrinsic factor. In a given case of infection, the virulence of the attacking germ and the fighting powers of the cell decline in equal measure until something occurs to help the one or the other, and then the germ is exterminated or the system suffers according to the preponderance of reinforcement.

Multiple Neuritis in Wood Alcohol Poisoning.—S. E. Jelliffe has seen three cases of this condition. Two of the patients suffered from the hyperesthetic form of neuritis. Both were painters and varnishers, doing nothing but shellac work. Neither were intemperate, and their symptoms were due, apparently, to breathing the fumes of the wood alcohol in which the shellac gum was dissolved. One of them may have been in the habit of drinking the alcohol diluted. The author reviews the chemistry of this compound, and in answer to the anticipated question as to why there are not more cases of methyl alcohol peripheral neuritis on record, says that there are a number of reasons. One is that death occurs so promptly in many instances that there is not enough time to develop the lesion in the peripheral nerves; or because of the greater susceptibility of the ganglion cells of the retina, partial or complete blindness appears so promptly that the methyl alcohol mixtures are not taken for a greater length of time. As for the reasons for this relatively greater susceptibility of the retinal ganglionic structures, it can be accepted at the present time only as a fact, bearing in mind that the alcohols as a class affect the more complex nervous elements of the cerebrum and highly differentiated special senses more rapidly than the comparatively more primary spinal neurons of the peripheral nervous system. Peripheral neuritis from wood alcohol does not seem to have been observed in any of the animals experimented on. Here again the early death precludes the development of the lesion, and, moreover, most of the investigators had in mind solely the effects to be observed in the retina and optic nerves. The more general subject of experimental wood alcohol peripheral neuritis is, therefore, in need of investigation.

Appendicitis, as a Visceral Manifestation of Erythema Exudativum Multiforme.—J. S. Chenoweth notes that visceral lesions have been frequently noted in this form of erythema, and that they may precede or follow the eruption and may cause a fatal termination. In certain cases the lungs, brain, kidneys, stomach, and intestines have been pathologically affected. These visceral lesions are not uncommonly attended by intense colic, high fever, nose bleed, hematuria, hematemesis, and intestinal hemorrhage, one or all of which may be present in any given case. Cases of this erythema may be ushered in by the so-called abdominal crisis, which resembles somewhat the initial stages of an appendicitis, or the true nature of the case may be recognized, but an appendical trouble overlooked, as accompanying vasomotor circulatory disturbances in the appendix may cause congestion and hemorrhages into its lumen, whence may arise infection, inflammation, or

actual gangrene. A point of diagnostic value in the author's experience has been the absence in the abdominal crises of exudative erythema, of muscular rigidity, and localized tenderness, except in those cases in which the appendix has been involved. Four cases are given in detail, and the clinical as well as microscopical study of them demonstrate the fact that the pathological condition in the appendix was primarily and essentially the same as that taking place in the skin. That the erythema was not secondary to the appendicitis is clear from the fact that previous attacks of erythema had occurred in two cases, and have occurred at intervals since the removal of the appendix. The occurrence of appendicitis in these cases is, of course, not to be regarded as due to the erythematous eruption on the skin but rather, as the title of this paper would indicate, as one of the visceral manifestations of that condition of which the presence of such an eruption is the most common and easily recognized sign.

American Medicine, March 4, 1905

The Mortality of Pneumonia in High Altitudes.—Charles F. Kieffer refers to the very common belief that pneumonia is more fatal at high altitudes than at the sea level. Several recent papers are reviewed. The paper is a study of the cases occurring at Fort D. A. Russell, Wyoming, at an elevation of 6,195 feet above sea level, during the period between 1868 and 1905. During this time among 26,569 admissions for all causes, there were 127 cases of pneumonia with 20 deaths; a mortality of 15.74 per cent. The fatal cases are classified according to the anatomic location of the disease. The writer calls attention to the prognostic import of syphilis on pneumonia. The figures are compared with those of the entire army. In the period between 1868 and 1893 the total admissions in the army for pneumonia were 7,078, with 1,105 deaths; a mortality of 15.61 per cent. During the same years at Fort Russell, there were 123 cases with 18 deaths; a mortality of 14.63 per cent., the advantage in favor of the high altitude being 1 per cent. Charts are included showing the incidence of the disease by months and a chart showing the mortality and ratio of incidence in the army for 36 years. The paper concludes that the figures, as far as they go, seem to show that altitude has very little influence on the mortality of pneumonia.

Puerperal Tetanus.—J. F. Roederer reports a case. The first symptoms of tetanus appeared on June 7, 10 days after the birth of the child. Eighteen days later (June 25) she had entirely recovered from tetanus. From June 7 until June 11 she had only clonic spasms. The clonic spasms began on June 12 and lasted until the evening of June 24, during which time she had at least 1,500 convulsions. During the first four or five days all the spasms, which were very severe, were accompanied by intense pain. After that the convulsions were not painful, nor were they so severe. Tetanus antitoxin was administered on 32 different occasions. In all 660 c.c. were given. The tetanus was succeeded by pain in the joints, eruption and high temperature which continued three weeks and were no doubt due to the same cause which gives rise to the pain and eruption which are met in some people a number of days after the injection of diphtheria antitoxin. The patient made a good recovery.

City Dust and Patent Medicine Advertisements.—Robert Hessler traces the relationship existing between the amount of infective dust in a city and the number, kind, and size of patent medicine advertisements in the newspapers. City dust differs from country road dust in the presence of spittle. In spitting and in taking patent medicines we certainly excel. Medical advertisements may be divided into three classes: (1) Patent medicines proper, of unknown composition and proprietary. (2) Those of quacks. (3) Of lotions, pennyroyal pills, syringes, etc. Patent medicines can be divided into groups, according to their use; the largest group may be designated as the dust group, because it refers to diseases and conditions that depend on infective dust. In patent medicine advertisements there is a large list of names that in most instances when applied by the laity in self-diagnosed cases, must be regarded as synonyms of dust infection; among these names are the following: Catarrh, colds, cough, grip, tonsilitis, pleurisy, rheumatism, backache, kidney disease, lumbago, muscular rheumatism, nervousness, biliousness, etc. Their names may be grouped by marking names of respiratory affection like catarrh, colds, cough, in red; those referring to rheumatic conditions in blue; nervous conditions in yellow, etc., a general idea of this dust group of patent medicine advertisements may be obtained. The amount of space occupied by medical advertisements varies greatly in different papers and in different countries. In Indiana newspapers the amount varied from 2.5 per cent. to 14.5 per cent.; dust advertisements varied from 1 per cent. in a comparatively clean city up to 10 per cent. in a dusty one. When one-eighth of the total space of a newspaper is occupied by patent medicine advertisements, whose existence rests mainly on the condition of the streets and sidewalks it may be well to inquire if there is not something wrong with that municipality. There is also a seasonal variation; low ebb is reached in the summer, high tides occur in the fall and spring. The hot rays of the sun and street sprinkling in the summer and the lack of free ventilation in winter are powerful factors. Patent medicine men may not know why their nostrums are in demand, but they know that it pays to advertise in certain towns—dusty towns, and where the spitter is unmolested. What the people save by not keeping their city clean they are compelled to spend in a vain attempt to counteract the evil influence of the dust.

The Journal of the American Medical Association, March 4, 1905.

Syphilis a Disease of the Innocent.—L. D. Bulkley states that this disease is too invariably considered disreputable and the methods of extragenital infection. No one is cercently acquired. He mentions its prevalence in past times and in certain parts of the world and its infection of whole communities, largely through family life. He quotes Fournier's statements regarding the innocent acquisition of syphilis, and says that in his private practice this was the case in 50 per cent. of female cases, and that in married women the percentage of innocent infection was quite 85 per cent. He notices the occurrence of the hereditary form and the methods of extragential infection. No one is certain, he says, of not being infected innocently. In view of these facts he urges that this disease be placed among the contagious diseases under the control of boards of health. He advises making it a punishable offense to communicate this disease knowingly. If these measures could be carried out, he believes that a great step would be taken toward restraining the disorder and preventing infection of the innocent.

Acute Yellow Atrophy of the Liver.—H. G. Wells and P. Bassoe have studied four cases of acute yellow atrophy of the liver. While they admit that these do not throw much light on the obscure subject of the etiology of the condition, they discuss this at some length and suggest that a better insight into this perplexing disease may be obtained through later investigations on autolysis or self-digestion of cells. They state that in acute yellow atrophy of the liver they are forcibly reminded of the processes of autolysis by the rapid absorption of the liver tissue which takes place with the appearance at the same time of the products of proteolysis in the urine. The slight involvement of the bile ducts is against the theory of an ascending biliary infection, and there are objections, such as the rarity of obstructions in the ampulla of Vater and the greater pressure of the bile as compared with that of the pancreatic secretion, to Quincke's ingenious theory of pancreatic digestion. The authors suggest that this condition may be explained by assuming the poisoning of the liver by some substance having a specific affinity for some vital ingredient of the liver cells, but not affecting the autolytic ferments of these cells. They contradict the statement often made that the chief change is fatty degeneration. The yellow color is not due to fat, but to bilirubin. In two of their cases in which frozen sections were stained for fat, a surprisingly small quantity of this substance was present.

Delirium as a Symptom of Hysteria.—Theodore Diller states that, while it is well known that delirium constitutes the final phases of classical attacks of major hysteria, the subject of insanity in relation to hysteria seems to be in a state of more or less confusion or doubt. This, he believes, is due to the fact that these cases are not studied in their whole course by the same men. The family physician sees the earlier symptoms, and the asylum physician the later manifestations. Diller says that some authors call certain mental symptoms hysterical when they are mild or of short duration, but apply the designation "insanity" to the same symptoms when they are prolonged beyond a certain time or when they become more striking in type. He quotes at some length from Janet on the subject of delirium as a symptom of insanity, and reports several illustrative cases. In one case a diagnosis of typhoid was made, but Diller considered it a secondary infection, favored by the condition of the patient. In all the cases reported there was more or less marked neurotic disturbance or shock, and he considers that the diagnosis of hysteria was justified.

Exploratory Abdominal Section.—John Young Brown insists on the importance of exploratory section in all cases of penetrating wounds of the abdomen, when multiple perforations exist, or when the blood supply is cut off resection of the bowel is imperative. For this purpose, in case of gunshot wounds, he considers the Murphy button the ideal method. In severe abdominal contusions, he agrees with Bottomley, that operation is generally advisable, especially when there is pain, tenderness and muscular rigidity. In cases of strangulated hernia, when there is any question as to the integrity of the bowel, he believes that resection

should be performed. The distended loop should be drained above the constriction. As soon as the gut has been delivered through the supplementary incision he clamps it off and ties a glass tube, to which is attached a rubber hose, into its proximal end, and then proceeds with the resection. This is time saving and drainage is effected without soiling the field.

The Lancet, February 25, 1905.

Mental Symptoms Associated with Heart Disease.—H. Kerr reports a case of valvular heart disease occurring in a man of fifty-two years, autopsy showing an enormously hypertrophied organ, with mitral and aortic lesions. The special features of the case center about the patient's mental condition, which presented, as initial features, depression, low spirits, and a suicidal tendency. Later, after admission to the asylum, he became suspicious. After a few weeks' treatment he became cheerful and sociable, and was able to take part in indoor games. With a relapse in his cardiac condition his mental state again grew worse, and before death he had become stupid and morose. Concerning the association of insanity and heart disease, the author notes that lunacy reports show the latter to cause about ten per cent of deaths occurring among the insane. In a large proportion of these cases the heart affection has, in all probability, but little direct relation to the mental condition of the patient, but in a certain number of cases mental symptoms are present which have a very definite relation to the cardiac condition, and conform to a certain clinical type. It is this fact which has led alienists to give a place in their classifications to the insanity of heart disease as a distinct clinical variety, with subvarieties according to the different cardiac lesions, and the above mental symptoms are the typical ones of this type of insanity.

A Peculiar Form of Chronic Hyperplasia of the Mucous Membranes of the Upper Air Tract.—A series of three cases is reported by Sir F. Semon, who refers to similar cases reported by others generally as sclerotic hyperplasia. The histological findings in some of the cases are given in detail. Semon is inclined to call the process as a chronic hyperplasia, simply omitting the designation "sclerotic," for in one of his own cases a spontaneous complete disappearance of all the infiltration took place after it had existed several years. He has no theory to advance as to the cause of this peculiar change. Tuberculosis, syphilis, and rhino scleroma seem to be out of the question. Different pathologists have practically agreed as to their findings under the microscope. In general they suggest those of the later stage of hyperplastic rhinitis, in that there is an overgrowth of firm fibrillar connective tissue and small-celled infiltration around the smaller vessels.

British Medical Journal, February 25, 1905.

A Case of Acute Lymphatic Leukemia.—W. D. Donnan reports the history of this patient, a boy of twelve years, who came under his care. The child had returned home from school for the Easter holidays, and his mother noticed a spotty rash on his chest. He seemed a little more languid than usual, and became rather short of breath after any exercise. Although he expressed himself as feeling quite well, there was distinct anemia, showing especially in the mucous membrane of the lips and palate. The tongue was coated, and a petechial rash was present on the chest and trunk, and distinctly marked on the legs. The heart was normal. The spleen was just palpable under the costal margin at the end of a deep inspiration. He remained in bed for a fortnight, with a slight rise of temperature, not exceeding 100°. There was pain and swelling in one knee. The petechiæ came out in crops. At the end of the two weeks a blood examination was made. The red cells numbered 1,600,000, the white cells 40,000, while there was 30 per cent. of hemoglobin present. A differential count showed that 99 per cent. of the leucocytes were lymphocytes. The true nature of the malady was then revealed. The patient was put on Fowler's solution. The spleen increased in size. There was no lymphatic enlargement. A rise of pulse and temperature was followed by a sharp attack of epistaxis, which recurred within a few hours. Apparently as a result of the hemorrhage, the spleen was much reduced in size, and could just be felt under the costal margin. The course was so rapid that it might be compared to that of a specific fever or septicemic process. If the onset of the malady is dated from three weeks before the boy was seen, the disease ran its course in six weeks. The symptoms were acute only from the first epistaxis—six days before death. It was impossible for the mother to realize the fatal character of the disease, as the boy sat up in bed talking with his brothers and sisters, and yet eight days later he was dead. In every case in which there is anemia and the symptoms are obscure, a blood count is an absolute necessity. The patient did not appear to die from loss of blood, but rather from an acute septicemia, with high temperature and a steadily increasing pulse. The epistaxis could always be controlled by plugging. The only sign in this case for several weeks was the presence of a purpuric eruption on the body. The white cells, as is usual in acute lymphatic cases, were almost exclusively large lymphocytes. Acute leukemia is generally of the lymphatic type, occurs in young subjects, is generally fatal in from two to four months, and is uninfluenced by treatment.

Ovariotomy in a Child.—J. Hope Reford describes this case. The patient was eleven and a half years old. She had a temperature of 101° F., and was suffering from colic in the lower part of the abdomen, with gastrointestinal disturbance. For the previous five months the patient had complained more or less of these symptoms, but within the last few days they had become much aggravated. There was fullness of the hypogastrium, and a tumor was plainly palpable, extending above the umbilicus, dull, fluctuating, very tense, and with outlines clearly defined. There was no dullness in the flanks, and the tumor remained unchanged when the bladder was evacuated. At operation the tumor was found beneath the omentum. Its surface was smooth, it was very tense, and filled the lower part of the abdomen. On puncturing, about one and a half pints of slightly blood-stained fluid escaped. The cyst was found to spring from the left ovary. A few recent adhesions to the intestines were easily separated by the fingers. The appendages on the left side were removed, together with the tumor. The right ovary was not disturbed, as it appeared to be healthy. On opening the tumor, a mass of hair appeared, revealing a dermoid cyst. This fact probably accounted for its development at such an early age. The patient made a good recovery.

Incubation Period of Mumps.—James E. Blomfield calls attention to the fact that in the Code of Rules for Prevention of Infectious and Contagious Diseases in Schools, the quarantine period of mumps is given as twenty-four days. He mentions a case in which, at the extreme end of the twenty-fifth day, after exposure, an attack of mumps began, though it could not be recognized as mumps till the twenty-sixth day. In various treatises, the limit of the incubation period of this disease is given as three weeks, while in two it is given as twenty-five days.

Berliner klinische Wochenschrift, February 13, 1905.

Misuse of Tendon Transplantation.—Oppenheim says that, although undoubtedly good results have been obtained in certain cases by the transplantation of tendons, the indications for the operation should be restricted solely to conditions in which the morbid process has run its course and is stationary. That sufficient care in selecting cases is not always exercised by operating orthopedists is shown by three cases which have lately come under the author's observation, in which the ill-advised attempt was made to correct by operation palsies due to progressive central lesions. The first case was one of progressive muscular atrophy, the second, one of chronic anterior poliomyelitis. The third patient was an elderly woman who had suffered for some time from pain and weakness in the left leg, for which a celebrated orthopedic operator did a transplantation, regardless of the fact that similar symptoms were beginning to develop in the other leg also. Oppenheim's examination, three months later, showed that the symptoms were due to pressure on the lumbosacral cord by a tumor, probably malignant, and this diagnosis was confirmed by radiography. He accordingly concludes that it is the duty of the surgeon before undertaking such an operation to assure himself that the patient's malady has come to a permanent standstill and is no longer progressive.

Palpation of the Appendix and Appendicitis Larvata.—Hausmann agrees with Ewald, Edebohls and others who believe that the normal appendix can in many cases be palpated without any great difficulty, and says that he has succeeded in thirty-six cases. Considerable practice is necessary and some patients are wholly unsuited to this examination by reason of thick or resistant abdominal walls, or through inability to breathe properly. The latter feature is important as it is neccessary gradually to force the examining fingers deeply down to the pelvic brim, and each advance must be made while the muscles are relaxed during expiration. In order not to impair the tactile sensibility of the palpating fingers the other hand should be applied to the back of the examining fingers and supply all the pressure needed. The cecum, ascending colon and ilium must first be identified and the the cord-like, more or less hard, appendix be sought for by moving the fingers back and forth along the pelvic brim. By this means it is frequently possible to detect enlargement or tenderness of the organ, and so make the diagnosis of masked appendicitis in cases without local symptoms, and often simulating other diseases.

Münchener medizinische Wochenschrift, February 14, 1905.

The Hemolytic Action of Photodynamic Substances.—Sacharoff and Sachs undertook experiments on the hemolytic powers of fluorescent and other similar bodies, in order to supplement the observations of Tappeiner, Jodlbauer, Edlefsen and others on sensibilization, protozoa, etc. The first tests were made with eosin, which was added in varying amounts to 5 per cent. dilutions of rabbits' corpuscles, and the tubes then exposed to the sun while a control set of tubes was kept in the dark. The latter showed no change at the end of two hours, whereas the contents of the former had undergone complete hemolysis even in the dilution of 0.00075 c.c. of a 1 per cent. eosin solution to 1 c.c. of 5 per cent. rabbit's blood. The fact that this activity is largely dependent on oxidation was demonstrated by adding sodium sulphite to tubes containing erythrosin, under which conditions no hemolysis took place. It was found that the hemolytic property was manifested only by fluorescent substances, but that the degree of fluorescence and of photodynamic activity was not proportional, some of the most strongly fluorescent bodies being less hemolytic than others showing less fluorescence. The non-fluorescent substances tested did not possess any hemolytic activity, in spite of the fact that several of them, such as nigrosin, fuchsin and methylviolet belong to the best photographic sensibilizers. The authors therefore conclude that there is some connection between fluorescence and photodynamic activity.

The Question of Acute Cardiac Dilatation.—Starck says that the possibility of acute dilatation of the heart accompanying exertion, followed by rapid return to normal size is still disputed, as various authors who have studied the question, both clinically and experimentally, have arrived at widely different conclusions. He describes the case of a student who was examined shortly before a student duel and again immediately afterward, when he was found to have enormous cardiac dilatation, which had, however, almost completely disappeared a few hours later. The patient had experienced similar attacks of tachycardia and cardiac pain after other severe exertions, such as bicycling, and the author attributes the weakness to a preceding typhoid and other infectious diseases. The enormous dilatation taking place at the duel, which gave rise to such severe distress as to compel interruption of the combat before it had lasted more than a few moments, must be ascribed to psychical excitement rather than to fatigue, as the muscular work had been only very slight.

An Automatic Mixer for Making Serum Tests.—Pfaundler describes a device by which it is possible to make twelve dilutions of mixtures of serum and culture for agglutination reactions, ranging from 1-4 to 1-8,000, in three minutes and without requiring more than 0.5 c.c. of serum. By the use of the Thoma-Zeiss blood pipette in conjunction with the apparatus, the necessary dilutions may be carried out using only a single drop of blood from the patient. The author's device consists of a glass stop cock having four short tubes radiating from it at right angles to its long axis. The valve plug is recessed so as to form a cavity holding about 0.5 c.c. which can be brought into communication with any of the four tubes. One tube contains salt solution, another culture, another the serum, and the fourth is the mixing chamber from which each dilution as made is discharged. The author claims as advantages for the method the convenience with which dilutions up to any grade may be made, the fact that the culture is never exposed to the action of a stronger concentration of serum than it is to be tested with, and that the same quantity of culture is present in each dilution, the small amount of blood required, the avoidance of all danger of infection of the operator with the culture, and the simplicity and cheapness of the apparatus which can readily be cleaned and disinfected.

Deutsche medizinische Wochenschrift, February 2, 1905.

A New Method of Epilation.—Kromayer describes a new principle for the removal of undesirable hairs, which consists in punching out little disks of skin with a rotary circular knife. The procedures usually resorted to for this purpose, comprising the application of pastes and pulling out the individual hairs with forceps, are unreliable and almost certain to be followed by recurrences of greater or less extent because the papilla is left behind, and even with the electrolytic needle many of the papillæ escape destruction. The attachments of the hair follicle to the cutis are fairly close, but the root itself in the subcutaneous tissues is but loosely fixed. The author employs circular cutters varying in diameter from .7 to 1.2 mm., which are driven by a treadle machine or a motor, and with which it is possible to punch out minute disks of skin, the resulting wound healing without leaving a scar. The method of application is to cut the hairs short and with a quick touch of the cutter to punch out a tiny piece of skin having a hair in its center, the knife being carried just through the cutis. The stump with the root attached may then readily be removed with forceps. The course taken by the knife should follow that of the hair, but usually the instrument need not penetrate to a greater depth than 1.5 mm. The pain caused is about the same as that attending the prick of a needle, and for sensitive patients freezing with ethyl chloride is recommended. Depending on the circumstances, from one to two hundred hairs may be removed at a sitting, and the author has gone as high as three hundred.

The Treatment of Pulmonary Hemorrhage.—Hochhaus says that slight degrees of pulmonary hemorrhage require rest in bed in a cool room with no one present except the nurse, so as to avoid all excitement or talking; cracked ice by mouth and the application of the ice bag to the affected side if it be known, otherwise to the heart. It is not certain that the external cold actually does influence the internal vessels, but at any rate it enforces quiet on the patient, and has a good moral effect. Of the hemostatic drugs, a tablespoonful of salt in a little water is an old remedy, and ten to twenty drops of the fluid extract of ergot, or the same dose of fluid extract of hydrastis may be given. Traube recommends 0.02 gm. of lead acetate every two hours, and Fränkel has found 0.5 gram capsules of oil of turpentine every six hours useful. The routine use of opium in these cases is to be condemned and the drug is to be employed only when persistent cough keeps up the bleeding. In more severe cases the subcutaneous injection of of 40 c.c. of sterile 10 per cent. gelatine solution is warmly recommended by the author, as well as hypodermic injections of ergotin. Bandaging the extremities helps to relieve the pressure in the lungs, and should be done in such a way as to impede venous return but not to check the arterial flow; in this way large quantities of blood may be stored in each limb. Immobilization of the affected sides of the chest by strips of adhesive plaster is also to be tried in obstinate cases. Quincke in an intractable case had Bier resect the two first ribs in order to cause collapse of the affected lung, with temporary cessation of the hemorrhage; Turban also tried this measure with similar results.

The American Journal of the Medical Sciences, Feb., 1905.

Copious Water-Drinking and Polyuria in Typhoid Fever.—Edward F. Cushing and T. W. Clarke have made some very interesting observations on this subject. They report the results of the administration of abundance of water to one hundred typhoid patients. They have found that unusual amounts of from a gallon to a gallon and a half of water, or even more, could easily be taken in the twenty-four hours by typhoid fever patients. This was accomplished by giving four ounces every fifteen minutes during the waking hours. This amounted to from eight to fourteen pints. Besides this, an ordinary patient received every two hours during the day, and once or twice at night, alternately six ounces of milk and six ounces of albumen-water. This amounted to about three pints more of fluid. These large quantities were well borne. A careful analysis of these cases has been made, and has been compared with a series of fifty cases in which this treatment was not followed. In relation to this treatment, the writers state that a copious elimination of watery urine at once follows, the degree of polyuria, day by day, closely corresponding to the quantity of fluid ingested. Patients are more comfortable by this mode of treatment, and toxic, nervous symptoms are lessened. The mortality, as well as the severity, of typhoid fever, they believe, is still further diminished by this method of hydrotherapy employed as an accessory to the cool-bath treatment of the disease.

Chloride and Water Excretion in Typhoid Fever, with Copious Diuresis.—Torald Sollmann and J. A. Hofmann have investigated several interesting features of urine secretion in typhoid fever, as influenced by the treatment described in the preceding article. They offer the following conclusions: The free administration of water to typhoid patients causes a large polyuria, exceeding three litres per day, and averaging over five litres. On isolated days nine litres are not rarely excreted. The percentage of chlorides and the total molecular concentration are much below normal, while the daily excretion of total dissolved molecules exceeds that of ordinary typhoid cases. The eliminating capacity of the kidneys is not injured in typhoid fever, nor by a prolonged polyuria. There does not appear to be any accumulation of fluid in the body, the excretion being very nearly parallel to the income. The quantity of urine is influenced by the perspiration, and to a lesser extent by catharsis. It seems probable that the perspiration is freer under the influence of the large administration of fluid. The temperature has no direct effect on the diuresis. Diuretics do not increase the polyuria, nor does the administration of calcium chloride appear to diminish diuresis. The effect of the polyuria on the chloride excretion, as compared with ordinary typhoid cases, consists in a diminution of the percentage and an increase of the amount excreted per day. Minor variations in diuresis affect the percentage, but not the daily output. Perspiration acts indirectly by in-

fluencing the diuresis. The course of the fever, the degrees of hyperpyrexia, and the convalescence appear to have no direct effect. The chloride excretion varies strictly with the chloride income. The effect of calcium chloride, however, is delayed and comparatively small. Agurin, sodium acetate and nitrate, and urotropin had no effect on the chloride excretion, but it was increased by iodide. Moderate nephritis was without effect. The excretion of water and chlorides in typhoid fever appears to obey the same laws as in health. But there is a greater tendency to chloride retention in the fever. The difference appears to be quantitative and not qualitative. It is greatly diminished by polyuria. The prolonged restriction of the chloride income appears to produce no deleterious effects, and the patients do not develop "salt hunger."

The Toxemia of Pregnancy.—Edward P. Davis declares that pernicious nausea is the earliest manifestation of the toxemia of pregnancy. Strong evidence has been advanced that a toxemic condition is the cause of pernicious nausea. Skilful feeding and absolute rest offer the most successful treatment for this condition, and when these fail, pregnancy should be interrupted. The writer, after suggesting various available methods in the investigation of toxemia, emphasizes the importance of the careful observation of the patient by the physician, without recourse to technical examination. In the toxemia of pregnancy, the liver is the organ most often diseased. Post-mortem findings show the most striking changes in the liver. The characteristic lesion in the liver of toxemia and eclampsia in mother and fetus is hemorrhagic necrosis, with multiple thrombosis. The part played by the intestine in the toxemia of pregnancy is well known. In this condition the thyroid gland is deficient or altered in activity. The writer declares that our best knowledge at present leads us to believe that the toxemia of pregnancy is not essentially of nephritic origin. While the study of the urine does not show marked renal changes in the toxemia of pregnancy, the examination of the blood is more conclusive. In these cases the blood serum is distinctly toxic, as can be seen by its effects on animals. The poison of toxemia and eclampsia has not yet been chemically identified. In treating this condition the details of hygiene must be observed. As to drugs, laxatives are indicated. Calomel is valuable in increasing the solid excretion. Salines often cause the dissolution of dried feces and the absorption of fecal matter. If the toxemia persists, not yielding to treatment, induction of labor must be considered. Saline waters, especially vichy, are valuable in preventing serious toxemia. Normal salt solution by hypodermoclysis or by rectal injection, is indicated in the presence of threatening toxemia. In this affection it must be remembered that the vital organs are undergoing extensive degenerative changes, and the toxemic woman is not safe with the termination of pregnancy.

The Clinical Manifestations of Hemorrhages in Eclampsia.—Ralph Waldo Lobenstine states that hemorrhagic manifestations in eclampsia are evidenced only in those cases suffering from an extreme degree of toxicity. Although he has made an extensive review of the literature, he has come to no accurate conclusion as to the frequency of this group of cases. Only a few isolated cases have so far been reported. The writer enumerates the chief symptoms, as follows: Profound toxicity, jaundice, abdominal distention, which is usually a prominent and early symptom, beginning as an epigastric distention, which gradually becomes generalized; this sign is of bad omen, and in eclampsia should always suggest the possibility of hemorrhagic complications; vomiting, which consists of clear fluid or curdled milk, then bile, and, finally, coffee-ground material or clear blood; pain and tenderness over the liver and hemorrhagic manifestations other than the vomiting of blood. The chief pathological features are the development of multiple hemorrhagic foci in the various organs, the development of thrombotic processes in many of the smaller vessels, and the formation of irregularly shaped areas of necrosis in the several organs of the body, especially in the liver. The writer does not believe that eclampsia should be spoken of as being either primarily renal or hepatic in origin. Rather, the lesions in these organs should be regarded as the result of and not the cause of a toxemia whose true nature is not yet known, but in which doubtless both the mother and fetus play a part. Five of the seven cases which the author reports died. Treatment consists in sedatives, emptying of the uterus, diuresis, suprarenal extract and calcium chloride in large doses, preferably given by rectum.

Pathological Study of a Case of Myxedema Associated with Tuberculosis of the Adrenals.—J. Ramsay Hunt gives the results of his study of a case of this nature in which the disease had been gradually progressing during a period of four years, so that the dermal and neural manifestations were well marked at the time of death. In reviewing the changes, he states that the most important and essential one consists of an extensive atrophy and sclerosis of the thyroid gland. The hypophysis cerebri was not the seat of any considerable compensatory hypertrophy. The coexistence of a chronic tuberculosis of the adrenal glands is a rare example of a pathological coincidence. The characteristic symptoms of Addison's disease were absent. There was well marked generalized arteriosclerosis. Histological examination of the central and peripheral nervous systems was entirely negative. It is strange that symptoms which are so grave, and which persist often for years, are not attended by permanent alterations of nerve structure, but it has been impossible to demonstrate in the central nervous system uniform structural change which could be taken as their basis. The effects of thyroid therapy in cases of myxedema give strong clinical evidence that the nerve element in this disease is not dependent upon organic changes in the neural structures of the body.

Posterior Basic Meningitis.—Henry Koplik has seen a number of cases of posterior basic meningitis occurring sporadically throughout five years of continuous hospital service. He has established the fact recently that these cases may occur in epidemics of cerebrospinal meningitis. In a recent epidemic eight cases of cerebrospinal meningitis were typical cases of posterior basic meningitis, admitted at various periods of the affection. Some of these cases were as young as four months of age; most of them were below two years of age. The previous history was negative in all of these cases. The onset in the cases below two years of age was sudden in all but one case. In all cases fever and vomiting were followed by rigidity of the neck, in some cases by convulsions. The temperature in cases which had lasted for some length of time would not range above the normal until close to the final issue. In most of the cases below two years of age, there was no change in the fundus of the eye. The leucocyte counts were, as a rule, low, similar to those noted in tuberculous meningitis, and of no diagnostic value. Lumbar puncture in posterior basic meningitis is not always successful in evacuating fluid. The chronic cases yielded negative results so far as microorganisms in the puncture fluid are concerned, and the mononuclear picture resembled what is seen in tuberculous meningitis. According to the writer's interpretation, there are two forms of basic meningitis. The first, which is primary, corresponds to the type described by Still, in which there is a primary inflammation of the meninges, caused by the diplococcus intracellularis of Weichselbaum, and the second, occurring in older children, in which the symptoms in no way resemble those of the cases described by Still. In the second type the disease may be complicated with pneumonia, or may be secondary to this affection. Certain symptoms may occur, however, which will point to a basic involvement, such as facial paresis and paralysis of the eye muscles.

A Case of Parinaud's Conjunctivitis.—William Campbell Posey, in describing this disease, states that the first symptoms are those of a mild case of granular or purulent conjunctivitis. The secretion is not very abundant, the lids are swollen, the conjunctiva thickened, and granulations appear, which are at first small and semitransparent, later becoming yellowish, then red and opaque. In most cases some of the granulations assume a polypoid character, and may attain one-quarter of an inch or more in length. The writer says that these granulations, hanging chiefly from the fornix, present a most striking appearance, and form one of the characteristic features of the disease. This affection simulates tuberculous conjunctivitis very closely. The simultaneous involvement of the glandular system, and the peculiar pedunculated character of the granulations in some cases, and the rather characteristic erosions which occur between the granulations will usually differentiate the diagnosis without much difficulty. In certain cases, however, histological examinations and experimental inoculations will be necessary to make the diagnosis absolute. The origin of the affection is unknown. The pathological anatomy is also still in doubt. Treatment consists in antiseptic lotions and cauterization with silver and copper. Excision may be practised when the granulations are large. In certain cases searing with the actual cautery may be necessary. Alterative ointments should be applied to the glands, and if suppuration threatens, hot compresses, followed by incision and drainage. The glandular involvement and the symptoms of general systemic depression seem to point to an infective process.

Typhoidal Insanity in Childhood.—David L. Edsall believes that while this affection is uncommon, it is not extremely rare. From his study of the literature, the writer finds that in an appreciable number of cases the insanity persists; that mania is but little more common than dementia, while melancholia is far less common, and that a very marked proportion of the dementias do not get well. Dementias following typhoid fever must be far more common in childhood than in adults. Dementias are of far graver prognosis when of marked degree than are the other forms of insanity. The simple delusions and hallucina-

tions, without other mental disturbance, seem practically always to get well. The writer states that it is almost impossible to make any satisfactory statement as to the actual frequency of typhoidal insanity in childhood. It is often far more difficult to determine with children that this affection is present, and when it began, than it is with adults. The course of almost all of the cases that the writer has seen was directly related to the condition of the general nutrition. A certain number are without doubt toxic in their origin. The histories of the cases show no consistent relation to the severity of the attack of typhoid fever. There is, however, often a story of marked reduction of nutrition. The writer believes that feeding should be as free as possible, even during the latter part of the fever, and particularly if suspicious symptoms remain present or develop, the food should be very rapidly increased during convalescence.

Annals of Surgery, February, 1905.

Acid Intoxication; Its Significance in Surgical Conditions.—A series of forty-five cases has been studied by J. A. Kelly, who observes that at present our knowledge of the conditions accountable for the symptoms present, and for the occurrence of acetone and diacetic in the urine, is yet in its infancy. It has been proved experimentally that it is not due to acetone circulating in the blood, as the same condition has been produced experimentally by other substances. The amount of acetone found in the urine is no index as to the severity of the affection. Whether the occurrence of the symptoms is due to a toxic substance acting on psychomotor centers, or due to pressure on these centers, has not been proven. This is only offered as a suggestion as to the causation. That there is some toxemia occurring is doubtless true; whether it is due to the presence of volatile fatty acids, to the rapid destruction of proteid matter, or to the rapid elimination of the alkalies is impossible to say at the present time. The object of the author is to report a series of cases in which the condition has been present in a large proportion; to call attention to the condition as it exists in surgical cases; to show that what has been considered as a rather fatal condition is present mildly in a variety of cases, and to hope that it will stimulate to some extent experimental and clinical investigation.

Volvulus of the Jejunum.—A case is reported by C. L. Scudder, his patient being an adult woman who, after a "boiled dinner," was seized with colic, nausea, vomiting, and loose bowels. She was first seen by the author on the third day of the attack, and was then in a condition suggesting peritonitis and impending collapse. Abdominal section revealed an almost black coil of the jejunum about two feet long, twisted at its mesenteric attachment. Upon untwisting this volvulus it was found to extend up to within about two inches of the beginning of the jejunum, and thence down for two feet. The condition of the patient precluded the possibility of further interference. The abdomen was closed and the woman died. The author notes the necessity of exact diagnosis as to the cause of abdominal pain, and believes that earlier intervention in this case would probably have saved it. Volvulus of the jejunum as high as was this is rare. Microscopic examination of the tissues removed showed obliterating thrombosis of the superior mesenteric vein, with hemorrhagic infarction of a portion of the jejunum.

Primary Urethral Calculus.—H. E. Wolf reports the case of a man of fifty years, who died of a general sepsis, with multiple visceral lesions. Autopsy showed a calculus in the urethra, which was overlooked owing to absence of symptoms pointing to involvement of the genitourinary tract. The calculus weighed a little over 23½ grammes, and was located in the pendulous urethra, its foremost point being 5.4 cm. posterior to the external meatus, and the rear end 10 cm. from the same point. Its shape was such as to leave a narrow slit, through which the urine could pass. Two specimens examined showed no sediment. Analysis is made of previously reported cases.

Case of Bone Transference.—T. W. Huntington publishes the history of a case which illustrates the possibility of supplying a tibial defect amounting to absence of nearly the entire diaphysis by the appropriation of a corresponding portion of its companion fibula. The defect was the result of an acute, infectious osteomyelitis occurring in a boy of seven years. The fibula was sawed at a point opposite to the lower end of the upper tibial fragment and attached thereto, and the divided end of the fibula was firmly planted in a cup-shaped depression of the tibia. Union was slow, but became solid in the course of six months. Three months later it was decided to transfer the lower end of the fibula to the lower fragment of the tibia. Bony union was secured, and the patient made a good recovery. The limb was three-quarters of an inch shorter than its fellow, but was of fairly normal contour, and the patient was able to walk with only the suggestion of a limp, and to join in the ordinary sports of his fellows.

Contrecoup Fracture of the Sternum.—The rarity of sternal fractures leads G. De Tarnowsky to report a personal case. His patient, a man of forty-three years, fell from a ladder, turning a somersault and doubling up his body. Examination showed, among other injuries, a distinct protuberance of the sternum at the level of the second and third chondrosternal articulations. There were no external bruises; exquisite tenderness was present and crepitus was elicited. The patient progressed slowly toward recovery, but one week later began to have cramp-like pains in both arms. It was judged that there was some pressure over the lower cervical vertebræ, but no deformity could be made out at that site, nor was there any external evidence of injury. Two weeks later there was a distinct palpable ridge at the level of the second costal cartilages, the lower fragment slightly overlapping the upper. The callus was dense. All the spinal symptoms disappeared, and the patient was discharged in a satisfactory condition. Sixteen cases previously reported are analyzed, and the condition considered in a systematic way as to etiology, pathology, diagnosis, prognosis, and treatment. The factors producing such sternal fractures are summarized as follows: (1) Falls on the head or shoulders press the ribs forward and upward, the range of motion increasing from the first to the seventh pair. (2) The clavicles may sometimes act as a lever and help to wrench the manubrium from the gladiolus. This is especially true in falls on the extended hands. (3) Intrathoracic pressure at the time of the fall exerts a positive pressure on the thoracic wall. (4) The second costal cartilages act as a wedge, tending to separate the manubrium from the gladiolus.

Symmetrical Inflammation of the Epiphyseal Beak of the Tibia.—By the term "beak," K. Winslow refers to one of the two centers of ossification of the tubercle of the tibia, which develops as a peculiar process, which projects downward from the upper epiphysis. This beak is separated from the lower center of ossification of the tubercle by cartilage up to the eighteenth to twentieth year, when the two centers become merged into one bony tubercle, as it is seen in adult life. The lower center of ossification of the tubercle does not appear until the twelfth year. He then reports the case of a boy of fourteen years, in whom there was an inflammation of these structures on the two sides. He had had, probably, a scarlet fever two years and a half previously, followed by joint lesions. The knees were said to have been very sore for some time (when the case was first seen by the author) and to "give way" frequently. After rest in bed, with fixation of the limbs on splints had been tried for a month, together with various other measures, as external applications of heat and cold, counterirritants, actual cautery, etc., without avail, the boy came to operation July 9, 1904. At operation there was found an area of softened, spongy, and much infected bone, perhaps as large as a silver quarter-dollar, covered with greatly thickened periosteum under the seat of each external protuberance at the head of the tibia. The softened, diseased bone was scraped away to a depth of perhaps one-third of an inch, and the periosteum and skin were approximated without drainage. There was no suggestion of any suppurative process. The wounds healed well without infection. Cultures taken from the scrapings proved sterile, and an emulsion of the same injected several times intraperitoneally into a rabbit gave a negative result. The scrapings did not afford suitable material for sectioning. The patient made a perfect recovery.

French and Italian Journals.

Post-Malarial Cerebral Syndrome.—Forli observed a young man in whom there was an undoubted cerebellar syndrome ending after two weeks in recovery, but returning at the end of a month of good health. The history of malarial fever, the enlargement of the spleen, and the absence of other organic or functional alterations which might cause the symptoms made him regard them as due to malaria. The immediate cause might be an anatomical lesion or a toxic action from the changes in the blood.—*La Riforma Medica,* February 4, 1905.

Treatment of Echinococcus Cysts of the Liver.—Biondi advises in unilocular cysts, single or multiple, if non-suppurating and not adherent, laparotomy, complete evacuation, injection of fluoride of silver in 1 per cent. solution, and suture of the liver and abdominal walls. If adherent and non-suppurating, evacuation without laparotomy and silver injection. In non-suppurating cysts with proliferating cysts, laparotomy, evacuation, irrigation with normal salt solution or disinfection with silver, suture of the sac. In single and multiple suppurating cysts, marsupialization after the Lindemann-Landau method, and silver irrigation. In small, free, pedunculated cysts, enucleation and suture. In an entire lobe filled with cysts and easily pedunculable, resection and suture. In case of alveolar echinococci not susceptible of radical treatment, excise as much as possible and treat the rest by injection of fluoride of silver.—*La Riforma Medica,* February, 1905.

Book Reviews.

THE INFLUENCE OF GROWTH ON CONGENITAL AND ACQUIRED DEFORMITIES. By ADONIRAM BROWN JUDSON, A.M., M.D., Orthopedic Surgeon to the Out-Patient Department, New York Hospital, 1878-1903; Statistical Secretary of the New York Academy of Medicine; formerly President of The American Orthopedic Association, etc. New York: William Wood & Company, 1905.

"THE object of this book," the author states, "is to emphasize the fact that prevention and cure are to be found in so managing a case and equipping a patient that nature-growth will be the principal factor in recovery." It is refreshing in these latter days, when the tendency is to rely exclusively on the knife to correct deformities, to have our attention called to the fact that, with a little judicious assistance, the natural processes can effect cures in children in the larger number of cases. And this method of correcting deformities has two important advantages. First, the gradual return of the limb to its proper position by natural forces secures a better adjustment of the bones to their changed relations than occurs when these bones are suddenly and violently wrenched from their displaced state and then forcibly held in their new position. Second, the treatment of deformities by "nature-growth," as the author happily terms his method, has this great advantage over operative procedures, that it enables every practitioner to treat his own cases with the more or less frequent advice of an expert in the use of appliances. It is on this account that we regard the work before us as a most important contribution to orthopedic surgery.

The text is written in a very concise and yet lucid style, with such necessary discussion of the causation, pathology, and indications of treatment of deformities as will enable every physician to appreciate the precise line of procedure in each case. Each instrument is explained with that amplitude of details in regard to its special features and its application to the affected part that will enable the busy practitioner to treat successfully the deformities which from time to time occur in his practice.

This work will prove very acceptable to those who have been familiar with the patient and successful labors of Dr. Judson in the field of mechanical surgery. Whatever allurements the more immediately brilliant results of operative treatment of deformities may have presented to others, he has never swerved from his devotion to nature nor lost faith in her conservative power in correcting her own errors when assisted by an intelligent mind and skilful hand.

BACTERIOLOGY AND THE PUBLIC HEALTH. By GEORGE NEWMAN, M.D., D.P.H., etc. Third Edition. Philadelphia: P. Blakiston's Son & Co., 1904.

THIS book presents a simple, general statement, brought up to date, of our knowledge of bacteria in their relations to the public health. It does not pretend to deal fully with laboratory methods or technique, but broadly treats the general subject covered by its title, and particularly the everyday problems of preventive medicine. The author is conservative and draws no deductions which are not substantiated by abundant proof. Altogether, the book is an excellent one and should be in the library of every health officer, who will find it a ready and safe recourse for reference.

DIE FÄRBETECHNIK FÜR DAS NERVENSYSTEM. Von Dr. BERNHARD POLLACK. Berlin: S. Karger, 1905.

THIS book is intended to serve as a guide for advanced workers engaged in the microscopical investigations of the central nervous system. It contains chapters on autopsy technique, on methods of hardening, imbedding, and staining the various elements of the nervous system, also on the change in the weight of the brain after preservation in various fluids. The present is the third edition of the work, and it has been brought up to date in conformity with recent progress in this field. Particular attention is accorded to the methods for demonstrating the neurofibrillæ, in accordance with the importance which this subject has lately assumed.

SURGERY OF THE PROSTATE, PANCREAS, DIAPHRAGM, SPLEEN, THYROID, AND HYDROCEPHALUS—A Historical Review. By BENJAMIN MERRILL RICKETTS, Ph.B., M.D. Cincinnati, 1904.

In writing this book, the author has examined all the available literature on the subjects mentioned, has arranged it chronologically and placed it in chapter form, each introduced by a brief anatomical description of the part and a historical review. The work represents an enormous amount of careful and painstaking labor, and will afford surgeons and writers a most complete bibliography of the surgery of the organs mentioned. It is in fact an elaborated index medicus, and the idea might well be applied to other branches of medical science.

GÉOGRAPHIE MÉDICALE. Par le Dr. E. LAURENT. Paris: A Maloine, 1905.

THIS book stands almost alone in the subject of which it treats. The author has endeavored to prepare a book of ready reference for intending travelers or for physicians who are consulted as to the effect of certain climates upon special diseases. The medical geography of France is discussed quite fully, and the detailed information about that country is very valuable. When the author comes to discuss the other countries of the world, however, his statements are more or less general and vague, and lack that exactness and fullness of detail which alone would render such a work as that under consideration one of much practical value. Dr. Laurent has made the mistake of attempting to compress within a relatively few pages a subject, the proper treatment of which would require many volumes. Still, his book has a certain value for "globe-trotters" and physicians sending patients abroad, and, so far as it goes, it can be recommended.

THE AFTER-TREATMENT OF OPERATIONS. A Manual for Practitioners and House Surgeons. By P. LOCKHART MUMMERY, F.R.C.S. New York: William Wood & Co., 1905.

THE appearance of a second edition within a year after the publication of the first, indicates that this book has been favorably received. It was written to fill a vacancy in surgical literature, and it has evidently met the indications demanded. It has not been found necessary to add very much to the original text, a section on smoking and drug habits in their relation to operative procedure has been added and the description of postoperative insanity has been enlarged. The chapter on shock and collapse has been revised and brought up to date, likewise that on abdominal surgery, especially the part dealing with the operation for appendicitis. This book constitutes practically the first effort to present this subject in a useful form for ready reference, for what has been written is found for the most part in a fragmentary form in the larger textbooks and scattered through medical journals. The author deserves to be commended for presenting a work of this nature to the profession.

MANUAL OF OPERATIVE SURGERY. By Dr. JOHN FAIRBAIRN BINNIE, A.M., C.M. Philadelphia: P. Blakiston's Son & Co., 1905.

WORKS on operative surgery have become so numerous during the past few years, that any accession to the ranks must demand some special reason for its publication. And we find that the present work is intended by the author as a manual in which there should be omitted, as far as possible, all descriptions of those procedures which are ordinarily thoroughly given in the usual textbooks on general surgery. Reference to amputation and ligation has been omitted, and such portions of genitourinary and rectal surgery as are treated in the textbooks are not taken up, neither is the operative surgery of bones and joints. The aim has been to be practical, to describe operative procedures as they are done on the living subject, instead of on the cadaver. In going over the book one is impressed by the fact that a large amount of material has been gathered into a small compass, much of which has hitherto been available only in scattered books and journal articles. The text is clear and concise, the illustrations numerous, simple and well selected.

THE COMMON LOT. By ROBERT HERRICK, Author of "The Web of Life," "The Real World," etc. New York: The Macmillan Company; London: Macmillan & Co., Ltd., 1904.

IN this work the author has given to the public another and a very valuable contribution to that order of fiction now in vogue, and of which there have been several notable examples of late years—so-called realistic—and truly so-called in the sense that they take us down into that arena of life where men actually move and work and have their being. In that rushing clamoring world of business, where men deal hand to hand with men, character is sometimes made, and often marred, but it is always tested, and it always tells, and it is good to be reminded that through all the rush and the dust and the din, the voice of the ideal is still to be heard, and that there are to be found men who heed it, and that to-day, as of old, "honesty is still the best policy" in many senses of the phrase. The mills of the gods grind so slowly to the perceptions of many of us, that our writers of serious fiction may be held as benefactors of their kind when they give us books as good as this one to remind us that they still grind.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON GENERAL MEDICINE.

Stated Meeting, Held February 21, 1905.

DR. CHARLES H. LEWIS IN THE CHAIR.

An Unusual Case of Chorea.—Dr. WM. B. NOYES reported a case because of its interest in emphasizing some of the unusual symptoms and causes. The patient was a girl, 23 years old, a foundling. She had suffered within a year with rheumatic pains in different joints. Five or six months ago she developed some skin eruption, which she called "hives," and which itched, but disappeared when she took sulphur. Her hair had been falling out. About four weeks before the doctor saw her she had a sore throat and white patches in her mouth. For some weeks she had been acting strangely and had threatened suicide. She made two attacks against her roommate. She cried frequently and her memory was said to be failing. Her speech was somewhat affected and her enunciating was slurring. Ten days ago she noticed a twitching of her arms, shoulders, and facial muscles. She had never had a previous attack of chorea. Her right arm was so numb that she could not use it. Her friends said that she had been delirious for several nights. When called the doctor found her suffering from general choreiform movements of the face, upper extremities, and legs, so severe that she could hardly walk or sit up in a chair. Her mental condition seemed to be hysterical. She was sent to the Columbus Hospital. On admission her nervous and mental condition seemed to be somewhat better. A soft, systolic murmur, presumably hemic, was present. The cervical and epithrochlear glands were enlarged. There were constant choreiform movements of the tongue and irritated patches under the tongue. There was a coarse macular eruption over the forearms and over the palms, which did not itch. The skin of the legs and body was free. The rash was diagnosed as an early secondary syphilitic eruption. Her mental faculties, excepting for her complaint of depression and suicidal impulses, seemed more normal, and memory and reasoning power appeared to be normal. For some days her temperature was 99° in the morning and 100° in the evening. Treatment in the hospital by antisyphilitic measures resulted in a rapid disappearance of the choreiform movements. The eruption entirely faded away. At the end of one month she was found to be pregnant, being four months advanced. This had caused her a little discomfort. Dr. Noyes said this report suggested two lines of thought; first, what mental symptoms were to be considered a part of the usual clinical history of chorea and when was a diagnosis of some independent complicating psychosis necessary; secondly, what was the relation of chorea to such etiological factors as syphilis and pregnancy. He said that an accumulation of the unusual types of chorea was convincing that besides the familiar forms of Sydenham's chorea there were a variety of symptomatic choreas with choreiform movements absolutely indistinguishable from those of ordinary chorea minor. We could be assured that we were dealing with Sydenham's chorea if we had the circle of the choreiform movements, a history of rheumatism and endocarditis. He said no one had yet disproved that Sydenham's chorea, as well as the symptomatic forms, were not secondary to toxemia, and the same statement might be made of an acute articular rheumatism. Concerning chorea magna, it might be safely stated that it was in reality no disease *sui generis*, but that it appeared at puberty from the influence of hysteria or simulation. Genuine psychoses and cerebral disease were responsible for part of the cases. Concerning chorea of pregnancy, while many gave a history of previous attacks of undoubted Sydenham's chorea in childhood, and the condition was seen as a rule among the young and frequently unmarried subjects, the prognosis was far more serious than in other forms, death being due to exhaustion. The movements in these cases were usually identical with those of Sydenham's chorea. Very few cases of chorea due to syphilis were on record. In the case reported the appearance of chorea, and of the secondary symptoms or eruption of syphilis, and the early stages of pregnancy were nearly simultaneous. Three weeks of antisyphilitic treatment caused the movements to entirely disappear.

Dr. J. FINLEY BELL recalled a case occurring in a poorly nourished woman, 35 years of age, in the third month of pregnancy, who was practically starving. The messenger said she was suffering from convulsions and he went to her prepared to remove a fetus. She had simple choreiform movements. The urine revealed a large amount of indican with diacetic acid and acetone. She was placed on a nourishing diet and eliminative treatment and she went through her pregnancy without further trouble. She had been absolutely without food for three days.

Contribution to the Alcohol Question.—S. P. BEEBE, Ph.D., presented this communication. He said that in view of the influence of alcoholic beverages, physical, economical, and moral, upon society, it was of vast importance that the truth in regard to their physiological effect be known and taught. The analysis of many preparations, such as patent medicines, showed alcohol to be present in quantities varying from 7 to 47 per cent. Certain proprietary foods for the sick were found to contain quantities varying from 10.6 to 23 per cent. His paper was chiefly concerned with the so-called moderate use of alcohol. The maximum quantity of alcohol which might be classed as a moderate quantity had steadily decreased during the past fifty years, and at present an amount corresponding to about six ounces of whiskey was considered to be near the upper limit of a moderate drinker. The recent experiments of Atwater and Benedict with the respiration calorimeter had shown that when the daily dose of alcohol does not exceed 72.5 grains not more than two per cent. leaves the body unchanged, the 98 per cent. being oxidized into carbon dioxide and water. Such being the case, the potential energy of the alcohol must be available for use in the body for supplying heat, doing work, or in sparing body tissue. The careful respiration experiments of Zuntz and Geppert had shown that the amount of energy used in its absorption was less than that yielded by its oxidation, leaving a net percentage for body uses as great as that yielded by other forms of food. Experiments of men who approached the subject from opposite opinions had led to the following concordant results: (1) Alcohol might take the place of some fat or carbohydrate in the food. (2) When taken to replace dynamically (*i.e.* a quantity of alcohol having the same potential energy as the food replaced) a given amount of fat or carbohydrate in a body unaccustomed to its use it caused for a few days an increased excretion of nitrogen. During these few days the body gradually acquired a tolerance for this poison and the energy from its oxidation was then available for bodily needs to the same extent as the food replaced. (3) Alcohol was an extraordinary food, to be used only in certain conditions when its oxidation might be of great benefit; but on no account should it be taken except when needed. The conclusion that alcohol might under certain conditions be a food substance did not argue that it should be used widely and indiscriminately. All of the conclusions from experiments regarding the food value of alcohol depended upon the determination of the total nitrogen excreted in the urine; such a determination could be made by methods that were beyond reproach, yet they did not tell the whole story of the effect of alcohol on the proteid metabolism in the body, for they gave no clew to the distribution of this nitrogen among the several normal constituents of the urine. Impairment of function might show itself in an abnormal distribution of the nitrogen among the several physiological constituents. In health, 85 to 90 per cent. of the nitrogen

showed itself as urea, 2.5 to 5 per cent. as ammonia, and 3 to 5 per cent. as uric acid. The alcohol might show its toxic effect by interfering in the forms in which the total amount was excreted. The writer then described a series of experiments which he had made along this line first with alcohol and then with port wine and ale. It was noticed that the increase of uric acid was proportionally much greater when the latter were used than when a purer form of alcohol was employed. Probably port wine had the reputation of being the worst form of alcohol which could be taken. The results showed that alcohol caused a disturbance of those processes which made up metabolism and that this disturbance was evidenced by changes in the distribution of the nitrogen among the several physiological constituents of urine. With one exception the same result was found in all subjects experimented upon. Alcohol caused an increase in the excretion of uric acid; the point of greatest increase being the fifth hour following the meal. The total excretion for the alcohol day was greater than that on the control days, showing that the increase following the meal on the alcohol day was not due to a mere hastening of the normal output for a few hours, to be followed later by a drop below the normal. This experiment also afforded evidence that urates were not swept out of the body fluids by diuresis. The three products considered in these experiments, urea, ammonia, and uric acid, were the most important end products arising from the proteid metabolism in the body. The experimental work done upon the relationship which these substances bore to one another, and to the metabolic processes by which they were elaborated, had furnished but little knowledge. The relationship which uric acid bore to the complex compounds found in the cell nuclei, its origin from these compounds during the processes of metabolism, and its partial destruction by oxidation in the body tissues, were matters established with a high degree of certainty. The final steps in the production of urea were still obscure, but evidence showed that its immediate precursors were ammonia compounds and that the hepatic cells were the active agents in the preparation. In pathological conditions affecting these cells a much greater proportion of the total nitrogen was likely to appear as ammonia. It seemed probable that the liver was an agent of the greatest importance in dealing with the exogenous portion. It seemed that the experimental results might best be explained by supposing that alcohol had by its toxic action on the liver cells incapacitated them to some extent. The rapidity of its absorption into the portal circulation exposed the liver to a higher degree of concentration of the alcohol than other tissues of the body excepting the stomach mucosa. A portion of the alcohol was prbably oxidized immediately on reaching the liver, but there must have been an appreciable time previous to its oxidation during which it might exhibit its toxic action. Certain fact indicated that the oxidative functions of the liver had suffered as a result of the alcohol. Alcohol taken without food caused no increase in the excretion of uric acid and purin bases; taken with food it caused an increase of these substances, which, with constant quantities of alcohol in the same subject, seemed to be roughly proportional to the amount of purin material taken in the food. In those experiments in which the ammonia was estimated it invariably showed an increase during the alcohol period and since the diet was constant this indicated liver incapacity also. These results were obtained with moderate quantities of alcohol and no digestive disturbance was noted, but the long-continued use of moderate quantities did cause such disturbance. He said it was rather a dangerous doctrine for physicians to be too strenuous in insisting upon alcohol being a food simply as a result of calorimeter experiments, where energy was considered.

Dr. Egbert Le Fevre said that in the treatment of gouty conditions the use of salicylic acid was said to have a profound influence in causing a marked excretion of uric acid and, therefore, this was one of the drugs to use in this condition, clearing the blood of the uric acid that was present in it. But in Von Norden's communication it was claimed that salicylic acid was a most dangerous drug to use. that the output of uric acid was not due to a clearing out of retained uric acid in the blood, but it acted as did alcohol in increasing the output by diminishing the oxidation. It seemed certain that drugs, such as alcohol, had the power of acting upon the liver, by changing the oxidation of the purin bodies or the xanthine products so called, and increasing the amount of elimination by diminishing the amount of oxidation. Therapeutically, Dr. Le Fevre said he was a firm believer in alcohol as a food product, increasing body weight especially in certain diseases, in fevers, and in septic conditions.

Dr. E. E. Smith asked Mr. Beebe how many experiments were conducted to show that a pure diet of alcohol did not increase the amount of uric acid excreted?

Mr. S. P. Beebe replied that but three experiments had been conducted to show this. Dr. Graham Lusk has reported a case of a man who took practically nothing but alcohol. The taking of 900 c.c. of whiskey produced absolutely no change at all in the amount of uric acid.

Dr. E. E. Smith referred to certain experiments he had made some time ago in which the amount of uric acid was increased, more than double; these experiments were conducted upon dogs; but a moderate dose of alcohol did not increase the uric acid. He thought a possible explanation of this might be found in the influence of alcohol upon the formation of acids other than uric in the body. It was known that certain organic acids were formed in the body and gave rise to an increase in the elimination of ammonia and the synthetic formation of uric acid. By its influence on digestion alcohol might occasion certain digestive disturbances and the formation of lactic acid.

Mr. S. P. Beebe said that if large quantities of alcohol were used, and for a considerable length of time, it would be reasonable to suppose that these digestive disturbances would develop, but in his experiments only moderate doses were used, and no digestive disturbances were to be observed. He said he did not mean to combat the therapeutic use of alcohol. He thought the physician should be careful in advising patients that moderate doses of alcohol were without distinct harm.

The Treatment of Renal Inadequacy Associated with an Apparent Nephritis.—Dr. William J. Pulley read this paper. He said that Edebohls claimed to be able to cure any kind of chronic nephritis coming under his classification, viz., chronic parenchymatous, chronic diffuse, and chronic interstitiitial nephritis, which to a certain extent embodied all kinds of chronic kidney inflammations. He said that Edebohls had stated further that "this cure is brought about by removing a barrier in the shape of a capsule proper, to the creation of a new and increased and more active blood supply to the diseased kidney. The removal of this barrier by decapsulation is followed by the formation on the most extensive scale possible of a new connection between the kidney and its fatty capsule." Dr. Pulley said that at least three observers who had had opportunities of observing and examining minutely kidneys that had been decapsulated some length of time before removal had denied that this new vascular supply was formed. Jewett, Cutler and Boncz-Osmolowsky found but little connection between the blood supply of the new formed capsule and the kidney. That a new capsule, denser than the one removed, was formed after decapsulation was sufficiently proven by the observation of several men, including Edebohls himself. He said that Edebohls had further stated that the probable manner in which a cure was effected was by this new blood supply removing by absorption the products of inflammation. This might be the case if the exudate was comparatively recent, but it was hard to understand in the case of chronic interstitial nephritis. The same might be said concerning the increased nutrition brought to the kidney epithelia by this new formed blood supply, but here the etiology of nephritis

was ignored, although the cause still existed in all probability, and would be just as potent as ever against this so-claimed new blood supply, resulting in a return of all the symptoms after a certain length of time. Dr. Pulley then referred to the paper of Dr. Winfield Ayres, which was read before the Urological Society in June, 1904, in which it was stated that beginning nephritis under certain conditions could be cured by lavage of the kidney pelvis, and cited several cases which had shown marked improvement after a washing out of the pelvis of the kidney. In looking over the cases of other observers he found the diagnosis of chronic nephritis was based principally upon finding urine containing casts, epithelial cells from the kidney tubes, and albumin. These methods of diagnosis, he said, might be very well for the quick cure of chronic nephritis by surgical or other means of local measures, but it was a question in his mind as to whether they were sufficient thoroughly to establish a true diagnosis of the condition. It was his belief that the diagnosis of the forms of chronic nephritis could not be made by a few examinations of specimens of urine collected at random, but other things must be looked into as symptomatology, diet, exercise, and the general physical condition of the patient. All causes especially which tended to congest the kidneys or put tension upon its capsule must be eliminated. It was his belief that these conditions might cause simply a disturbance of the kidney function, probably by producing an increase of the kidney pressure and tension of the kidney capsule. In other words, many of these cases giving symptoms and secreting urine of a kind to make some believe they indicated a true chronic nephritis, he believed to be simple renal inadequacies, probably resulting from some mechanical obstruction; when this obstruction was removed the kidney would do its work properly, but was not cured of any chronic nephritis in the true sense of the word. It was incredible to him that when a true nephritis from any cause had advanced to that stage where the urine contained constantly casts of different kinds, with a lessening of the urea and solids, with a pronounced anemia due to chronic poisoning, that any surgical procedure or local treatment, could cure the pathological process that must necessarily be present. Decapsulation, or even lavage of the kidney pelvis, might produce a temporary relief at certain stages and in certain forms of chronic nephritis where the tension of the capsule simply increased the symptoms, but that was all. After reading Dr. Ayres' statement regarding his results in washing out the pelvis of the kidney, he began a systematic treatment of a number of cases by his method. The recital of a number of cases here followed, as well as the history of one of Dr. Ayres' cases. In conclusion, Dr. Pulley said that it was his belief (1) that chronic nephritis was never cured by purely surgical procedures or any kind of local treatment so far known to him. (2) That many symptoms of chronic nephritis which were due to an increase of internal kidney pressure could be relieved by decapsulation. (3) That many so-called cases of chronic nephritis were simply mechanical interferences with the normal kidney function, and that the inflammatory process, if any, was of secondary importance. (4) That lavage of the kidney pelvis was limited in its good effects to two conditions only, viz., pyelitis from any cause which affected the functions of the kidney by increasing its internal pressure, and secondly in parenchymatous and diffuse nephritis where there was a great deal of cellular débris, a concentrated urine, increased kidney pressure and tension of the capsule. He hazarded the explanation that the seemingly good results obtained by kidney lavage in pyelitis were due to clearing the pelvis and ureters of irritating substances, and in the parenchymatous and diffuse nephritis, principally by influencing the blood supply of the kidney, accelerating a sluggish current, expelling more or less stagnant blood, thereby bringing to the kidney fresh blood, which in turn stimulated the kidney epithelia to more vigorous action, and reducing the internal kidney pressure and capsule tension, thus tending to reestablish the normal conditions. The treatment consisted simply in passing catheters by means of the cystoscope into each ureter once or twice a week and washing out the pelves of the kidneys with a warm aqueous solution of nitrate of silver, 1-5,000 or 1-10,000 strength. The proteids were cut from the diet and the patient kept at rest. The only medication given were cathartics, and Basham's mixture three times a day.

Dr. Winfield Ayres said that in cases of degenerated tubule cells not due to irritation of a probably beginning nephritis, where there was a pyelitis and a possibility of its extension from the pelvis of the kidney up into the kidney, lavage would cause the tubule cells and albumin to disappear. He said he had tried it in forty-three cases of this kind, and in all but five it caused to entirely disappear all the tubule cells, the albumin, and the urines entirely cleared up. Some of these cases had been under observation for five or six months, with no return of cells or albumin, and he thought they were absolutely cured. Lavage of the renal pelvis, he said, would not cure a chronic parenchymatous nephritis, but it would relieve the symptoms to a marked extent. He had tried it in three cases of interstitial nephritis with some improvement. Lavage should be given at first once a week, and if the urethra would stand it, twice a week, but never oftener. After the first lavage, he said, there usually followed a distinct colic, which a dose of morphine would relieve, and which usually did not return, and this, in all probability, was due to spasm of the ureter. He said he had performed this operation 2,500 or 3,000 times, and that the time required to pass the catheters into the ureters and withdraw the cystoscope, leaving the catheters in place, was probably five minutes, and the entire treatment of one case required about one hour.

Dr. J. Finley Bell cautioned against the possibility of an ascending infection, carried from the urethra or bladder up into the ureters.

Dr. William N. Berkeley said he believed that in twenty-five or thirty years from now, when the physiology of the kidney would be worked out in the laboratory, our present views would be changed, and there would be some place to locate these cases which did not belong with acute, or subchronic, or inflammatory processes of the kidney, such as could be found in pathological examinations of the kidneys, when the post mortems were made within six to fourteen hours after death. A medical director of one of our largest insurance companies told him recently that he rejected all cases if the urine contained albumin, because he knew of no way to discriminate between the ordinary albuminurias and cases of true nephritis.

Dr. E. E. Smith asked what constituted a nephritis, and he agreed that there would occur a revision of our present conception of its nature. The presence of albumin and casts in the urine was evidence of a renal degeneration, or a degenerative process of renal parenchymatous tissues, but one should not conclude that that constituted a condition of progressive renal disease.

Dr. Charles H. Lewis said that to make a true diagnosis of chronic nephritis required a number of careful examinations and much time; many things should be carefully considered before making a diagnosis of chronic nephritis. Interstitial nephritis he had never considered a disease, but rather a sign of age. The kidneys would wear out, and in old people one could usually find albumin and casts if carefully examined for. Dr. Ferguson had told him that he never saw a healthy kidney in a person over fifty years of age. Dr. Lewis believed that a nephritis would carry away all of us after seventy years of age unless we died of some other disease.

Landry's Paralysis.—Charles F. Wiley reports an interesting case in a young man of twenty-four, who became ill July 2, 1904, which terminated in a fairly good recovery. Up to the present time, however, in spite of treatment, the lower back pelvic and lower extremity muscles are still inactive.—*American Medicine,* March 5, 1905.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 23, 1905.

DR. CHAS. F. ADAMS, CHAIRMAN.

An Undetermined Tumor in the Interior of the Uterus.—Dr. GEORGE H. BALLERAY presented a uterus that he had removed from a patient five weeks ago. The woman was 47 years old and had never had any children. During the past year or two her periods had been very irregular, going over time, until six months ago when she had more or less metrorrhagia. This bleeding occurred at very irregular intervals; there was a considerable amount of blood lost, watery in character, and with a distinct odor. The patient was very much emaciated when she entered the hospital, she had some elevation of temperature, cough, and coryza. During her first week in hospital her temperature rose to 103° and 104°, and then subsided. Her general condition was below par. Malignant disease of the body of the uterus was suspected, but when the high temperature developed he thought she might have had simply an attack of influenza. He then thought of the possibility of tuberculosis. At any rate he determined to remove the uterus. The uterus was found to be bound down not only to the adnexa, but to the intestines, the adhesions being as dense as any he had ever encountered. During the operation her condition became exceedingly bad, and it was found that she was practically a "bleeder," although no such history was obtainable. So much blood was lost during the operation that she became pulseless. In spite of stimulation and transfusions she remained pulseless, bleeding from the vaginal tissues so profusely that he believed she would die on the operating table. The blood seemed to well up from the tissues. The tissues were clamped with a hysterectomy clamp and left in situ, and the wound was packed and the patient removed to the bed. The next morning the pulse was perceptible, and was 160. On the second day it ran from 140 to 130, and on the third day vomiting set in, at one time fecal in character. The stomach was washed out, the bowels were irrigated, stimulants were given, and the patient then went on to an uneventful recovery. He regretted that a microscopical examination of the specimen had not been made. The tubes, especially the right one, was very much dilated at the time of removal.

Double Pyosalpinx With No Clinical Symptoms.—Dr. GEORGE H. BALLERAY presented a specimen of the uterus and adnexa which he had removed from a woman 36 years old, the mother of six children, and who had had one miscarriage. The last child was born last March, and the labor was difficult, the patient making a slow recovery and remaining quite anemic, and she was not considered to be in good condition until January last, when she entered the hospital, her physician supposing she was suffering from an attack of appendicitis. After a week the symptoms subsided. A mass was found on both sides of the uterus, and there was a very bad tear of the cervix uteri. Last Monday she was operated upon. The laceration in the cervix was very extensive, extending into the perimetrium, and there was so much cicatricial formation that it bound the uterus down. An abdominal section was done; both adnexa were found diseased and the uterus firmly bound down. The tubes contained pus which, during manipulation, escaped into the pelvis and was mopped up as fast as it escaped. The specimen, he said, was interesting in showing to what extent structures might undergo disease and yet give so few signs. The masses on the sides of the uterus were the size of the closed fist. This patient died of secondary hemorrhage. During the operation there was very little blood lost, but the shock of the operation was great. She died three-quarters of an hour after the first symptoms showed themselves. The hemostasis was most perfect in this case. He reported this case to emphasize his belief that hysterectomies should not be advised so indiscriminately. He acknowledged that he could not keep his mortality of total abdominal hysterectomies below 10 or 12 per cent., and for that reason he did not believe in advising patients to submit to operations of this kind unless the indications were very clear. It was the condition of the cervix itself which caused him to do the operation, for it seemed to be bordering on malignancy.

Dr. ARNOLD STURMDORF said that Dr. Balleray's mortality would never be lowered if he continued to wait. He said he could recall two cases in which secondary hemorrhage occurred after special precautions had been taken to prevent it, but he had been [illegible] patients were removed from the operating room. The slipping of the ligatures was not due so much to faulty tying, but to the edematous condition of the tissues at the time of ligation. The severance of the tissues caused a reduction in the mass and slipping of the ligatures. The blood vessels at the roof of the vagina were too small to be caught, and at times the rigidity of the tissues prevented their being caught. He said that two cases had been reported where adrenalin had been given, but death resulted from secondary hemorrhage in spite of it.

Dr. Balleray said the slipping of the ligatures was, in all probability, caused by the lessening in bulk of the tissues following incisions into them. With regard to operating more often upon fibroid cases, he thought that possibly he might get a smaller mortality, but he did not feel that he was warranted in operating upon such small fibroids because so many of these patients went along without any trouble at all; whereas, if he had operated upon them he would have subjected them to a certain risk. In the case he reported he said there was no doubt at all about the diagnosis of fibroids. He had seen tumors of this nature disappear after pregnancy when, at the time of delivery, they were large enough to obstruct delivery. In 1886 he read a paper before the Medical Society of the State of New York, in which he detailed several such cases.

Ruptured Cyst of Ovary from Twisted Pedicle; Hydrosalpinx on the Other Side.—Dr. S. MARX presented this specimen, which was of peculiar interest in showing how little one knew of what was going on within the abdomen until it was opened. The patient from whom the specimen was removed was 25 or 26 years old, who had had, five or six years previous, a very difficult labor and severe laceration. The laceration was operated upon six months after delivery, but it was followed shortly after by a prolapse of the second degree. The pessary treatment was tried, but she could not stand the discomfort. When Dr. Marx saw the patient there was an intense pain in both groins, and an examination revealed a prolapse of the uterus, and this organ was absolutely fixed and he wondered how a pessary could have been worn at all. He advised an operation. Examination showed a tumefaction about the size of the closed fist to the right of the uterus. When the patient was admitted to the hospital she had a normal pulse and temperature. The operation was an elective one. When the patient was examined under the anesthetic no tumor presented, and he took it for granted that a wrong diagnosis had been made, but he decided to open the abdomen anyway because of the firm fixation of the uterus. In the abdominal cavity he found a mass of blood and also a gangrenous cyst of the ovary which had ruptured into the abdominal cavity; the coppery-colored mass was this gangrenous tumor due to twisting of its pedicle. An examination of the other side revealed a hydrosalpinx. The gangrenous tissue was sewn up, and the patient, in spite of this procedure, made a rapid and uneventful recovery. Dr. Marx said this case proved how little one knew of what was going on in the abdomen until it was opened and inspected.

Is Craniotomy on a Living Child Ever Justifiable?—Dr. S. MARX read this paper. He said that this subject resolved itself into a discussion on craniotomy versus cesarean section, or symphyseotomy. Other things being equal, the religious question always weighed strongly, and more often than not absolutely determined the result; the writer

always favored the mother as compared to the unknown fetus. This finality had been arrived at even in the face of the wonderful results of modern surgery. His experience had forced him to the belief that only in rare cases could we consider a cesarean section in the woman many hours in labor, after manifold attempts to deliver, in the presence of a suffering fetus as more conservative than a skillfully performed craniotomy. The sphere for craniotomy was limited, but the limitations ought to be extended, always holding that the life of the dangerously ill mother was of greater value than that of the suffering and possibly badly maimed child. The absolute contraindication for the performance of perforation was offered in pelves absolutely contracted from either bone approximation or the presence of a tumor mass. If the patient was near term an elective cesarean section would be the method of choice. Too often such a condition was not known until the woman had been many hours in labor. This occurrence could be obviated by timely care and attention to the pelvic construction of every gravid woman.

Any prolonged difficult life-saving operation on the fetus was contraindicated when the fetus was known to be suffering profoundly, as was shown by well-known physical signs. After a baby had, by severe handling, had its tender skull and brain probably vitally injured, its advent dead was preferable to a life of suffering or idiocy. This calamity could be avoided in a number of cases by early discovery that a malposition or a pelvic contraction existed. A contracted pelvis of the profound type was always more readily discovered than a simple occipito-posterior position. Here under this category he preferred the perforators. The perforators were also absolutely indicated in cases of known vital deformity, such as huge hydrocephalic and other monsters. As to absolute indications regarding the mother, he said that the wishes of the parents and of the immediate family ought to be satisfied. Where dire and sudden accidents arose which threatened the life of the mother, and where the child could not be extricated except after prolonged efforts which would tend to extinguish fetal life, that unless a rapid forceps, version or extraction could be done, our duty ought always to be the performance of a perforation. He embraced only such grave complications as pulmonary embolus, severe accidental hemorrhage, eclampsia, etc. The destructive operation was absolutely necessary in cases of grave exhaustion, when the woman had been the victim of a prolonged fruitless labor with powerful efforts to deliver under prolonged anesthesia, and who would be unable to stand a cesarean section. He thought that better instruction, skill, and patience on the part of the accoucheur would do more to anticipate these calamities and prevent them than myriads of warnings uttered after the complications had occurred.

The skilled and perfect accoucheur could, by adopting various means and measures, reduce the necessity for the performance of the destructive fetal operations to a minimum. The early recognition of fetal exhaustion, the careful watch for threatening and impending maternal dissolution, were sacred and initial duties of the conscientious man. Operating too early without indications was as criminal as operating too late. Timely interference in the presence of clear indications, of normal presentations, knowing whether or not there was a disproportion between the fetal head and material structures, were all the purest quintessence of common sense. Recognizing early vicious presentations, and their timely correction, was but one of the manifold duties of the physician. The various positions could often be utilized for ready and easy delivery as the lateral prone, the Trendelenburg, and the Walcher; with the latter he had had the greatest satisfaction. The physician ought to decide, when the question is left to him, in favor of a major operation when the child was in good condition, or approximately so, and when the mother was not septic and able to stand the shock of such an operation. If there was the slightest doubt as to the outcome, we should favor perforation of the living child. Unless cesarean section could be made reasonably safe, he unhesitatingly preferred craniotomy. While cesarean section was safe in skilled hands, perforation was less dangerous in unskilled hands. The question was most difficult to decide in those cases in which the pelvic contraction was of the minor type. If not recognized they formed a series of dystociæ that tested the skill of a careful observer. These could be overcome in many women by the early performance of version, the after-coming head helped through the pelvis by the Walcher position and firm suprapubic pressure. When version was impossible through early rupture of the waters, the tentative use of typical or atypical forceps, using the extension position, might be of value. The application must not be too long or too powerful. If the woman and child were then in good condition, and this was found to be unsuccessful, and the patient was in such environment that the favorable outcome of an operation was reasonably certain, then only would a cesarean section be allowable. He said that experience in his own work led him to believe that the field for perforations and the allied operations was widening, and that for cesarean section was narrowing.

Dr. Egbert H. Grandin said that this question had been brought up very frequently, and had uniformly been answered as it had been by Dr. Marx. He said he did not see how it could be answered otherwise than it had been ten or fifteen years ago. At the bedside one was brought in contact with so many prejudices, sometimes of a religious character, but always in favor of the life that had the greatest right to exist. In private practice one was certainly rarely allowed to do in those border-line cases what one should like to do, *i. e.* avoid the destroying of the fetus. Often the fetus must be destroyed. He said the discussion was not dealing with those absolute pelvic contractions, or with tumors in the lower uterine segment, or those cases wherein cesarean section was necessitated; but on those border-line cases—cases in which no man could say positively that forceps or version would enable one to avoid both cesarean section and embryotomy. If obstetrics was an exact science, then we could say positively that embryotomy on a living child was never justifiable. He said he had been invited once to witness a cesarean section, but before the doctor reached the hospital the woman had delivered herself. He said that if we had to wait until version had been tried, until forceps had been applied, and until the woman had more or less exhausted herself, as well as the fetus, and then perform a cesarean section, it meant the death warrant of both mother and child. In 1890 he said he had read a paper before the American Gynecological Society in the course of which he reported two instances of cesarean section, the operation having been done in both from an elective standpoint, with maternal and fetal recovery, and he then made the statement that the time was not far distant when we would cease to be called upon to destroy a living fetus. To-day if called upon to decide the question whether we would subject the mother to the dangers of a cesarean section, because we could not always get a man trained sufficiently in the performance of this operation, even though this operation might be the easiest of all. If a man knew *how* to suture the uterus, this operation, in his opinion, became a very easy one. Embryotomy and craniotomy in the hands of an expert usually carried no death rate in these border-line cases; but this was not so in the hands of those who were not experts. Craniotomy and basiotripsy might become the gravest of operations by the injury done the woman. To-day Dr. Grandin said we must be satisfied in informing the husband that we can get a living child if a cesarean section be allowed, which would only subject the woman to a one-half per cent. death rate. Yet most husbands would say that embryotomy should be performed.

Dr. Malcolm McLean said that, after years of experience in this work he felt as Dr. Grandin did. When brought face to face with these questions we should consider them from a scientific standpoint, and ask ourselves what was the proper thing to do under such conditions as

have been placed under the name of "border-line" cases. Therefore he accepted what Dr. Grandin and the reader of the paper had stated, and that was the position he had held for years. Still, he said his repugnance against the operation of embryotomy was so strong that he felt it was only right that he should express his personal experience, and that was that he had never yet done this operation. That did not mean that he had dodged his duty to his patients, but that he had taken pains to circumvent so undesirable an operation; he had had unusual luck in his cases. Scientifically speaking, he said that he could imagine cases—cases brought to his notice after other methods had been tried—where he could not have an early choice in the matter, where the mother was in such a condition that she could not stand the operation of cesarean section; under these circumstances, when he was confronted with the question of a living child or a living mother, he would have to subject these facts to the husband, or parents, or friends in such a way as to throw the responsibility upon them of preventing him from doing what he considered a scientific operation. When confronted with such questions he believed the life of the child should give way to the life of the mother. These cases he believed to be rarer than one would infer from the discussion and paper; he did not believe that many cases would present themselves to us if it was taken into account that we could avoid such an operation. He had seen the operation done under conditions when it was so unnecessary—and in good hands, too—that he had held himself back and tried in every way to see if he had done everything that should be done in every case. Therefore, he said he had never been obliged to do the operation, because such cases had never presented themselves to him.

Dr. Austin Flint, Jr., said he came prepared to take the ground that embryotomy did have a place in obstetrics, although he believed that it was an operation that would be done less and less, because of a better understanding of conditions existing earlier in these cases. The whole question he believed had to do with the diagnosis; to-day one did not seem to be able to tell whether a particular head would come through a particular pelvis. Under certain conditions it certainly did seem better to perforate the head rather than to wait for the child to die. These questions that come up, he said, must be studied and a decision made from the personal equation of the man, from a religious standpoint and other standpoints. It must be at times performed, although with great reluctance. The ability to make an early diagnosis and submit the patient to the cesarean section early he believed to be the better procedure in these cases.

Dr. J. O. Polak said that it was unfair to place the operation of craniotomy against any elective operation, because this was, in truth, an operation of emergency. In tenement-house practice one met with these cases, and craniotomy was theoretically antagonistic; still it must be done. He said he was much interested in the cases called accident cases; here craniotomy had been of great service to him. For instance, take a case of eclampsia, with a fetus that was just viable, with the woman in a very serious condition, dilatation of the parts not being satisfactory; one not infrequently could reduce the size of the head and facilitate delivery by doing a craniotomy. He said that all could conceive those border-line cases where the woman's life could be saved by reducing the size of the passenger. If a diagnosis of these cases could be made early, and an attempt made, by moulding, etc., to force the individual head to fit the individual pelvis, he believed there would be no necessity for doing embryotomy. The cases in which we were called upon to decide between craniotomy and cesarean section, as a rule, were infected cases, where the forceps had been tried, or some internal manipulation, and these were the worst possible cases.

Dr. J. D. Voorhees made a more vigorous plea for the cutting operation, although he agreed in the main with what had been said. Craniotomy on the living child had its place, especially in such cases of pregnancy complicated with acute pelvic disease, with toxemia, placenta previa, chronic endocarditis, etc., where the mother's life was in jeopardy. Craniotomy was justifiable in cases of monstrosities or hydrocephalus. Take, for instance, a case where the mother was in good condition, but the child in a very poor condition; the forceps had been applied and the child showed signs of asphyxiation; in such a case the child no doubt would be sacrificed if delivery by the ordinary route was attempted. Again, take a case with a considerable degree of contraction, where the forceps had been applied but nothing accomplished; under proper surroundings cesarean section should be performed. But if the mother was in poor condition with a tonic uterus, and the child dead or moribund, craniotomy should be the operation of choice. Where both mother and child are in good condition, under proper surroundings, when the question came up between craniotomy and cesarean section, if cesarean section was decided upon then the greatest objection came, as a rule, from the patient or from the relatives, and consent might not be obtained for a cutting operation upon the mother. The difficulties in diagnosis were emphasized. Cesarean section he considered to be an easy operation, but it should be performed early. He referred to Dr. Cragin's operation upon two private patients at the Sloan Maternity; both made a smooth convalescence. As time went on he believed that cesarean section would be done more frequently, and, in some cases, patients themselves will request that it be done.

Dr. George L. Brodhead said he was in perfect accord with Dr. Marx's remarks. All agreed as to the relative and the absolute indications, and the question really came down to a choice of method in those cases which presented relative indications for craniotomy or cesarean section. In those cases in which the question came up he said that, at the beginning of labor, as a rule, no one had the faintest idea that either operation would have to be done. They hoped to get the child out by forceps or version, and the idea of a craniotomy being called for never entered their minds. The head then would not descend, and forceps were applied, but without success; then perhaps version was performed; then it would be discovered that delivery would have to be accomplished by other methods. By this time the child's heart would be found to be very feeble, and it was in these cases that embryotomy was to be chosen rather than cesarean section. The majority of these patients presented themselves too late for cesarean section to be performed successfully.

Dr. George H. Balleray said there were cases in which there was an absolute indication for cesarean section, and others in which this was not so clear. In those cases in which attempts to deliver by forceps, version, etc., had been tried, and the infant's life was in jeopardy, then craniotomy was indicated. In the hands of men who were not experts in abdominal surgery craniotomy had better be attempted. He did not believe cesarean section was as easy as some supposed, and it should not be attempted by the tyro. He believed, however, the time would come when craniotomy on the living child would not be indicated as often as it was to-day.

Dr. S. Marx said that he regarded cesarean section one of the simplest operations in abdominal surgery, and that he would rather do this operation than do a perforation or even a difficult forceps delivery, because no strength or time was wasted, and the only danger was from sepsis. Dr. Polak had informed him that in 15 cases of cesarean section the amount of blood lost in each case was less than would have occurred during a normal labor; these cases occurred at the Long Island Hospital. He said there were four men present who were instructors in obstetrics in colleges; if these men would instruct their students more in diagnosis the problem would be solved. He believed there was more bad midwifery in the City of New York than any other city; and this was, in all probability, due to the fact that there were so many physicians here, or

else because women were so prolific. He said that Dr. Voorhees was inclined to favor cesarean section as opposed to craniotomy; but he called attention to the fact that all did not have the advantages the Sloane Maternity offered in the way of skilled assistants, etc.

Pathological Society of Philadelphia.

At a stated meeting, held February 23, Dr. C. Foulkrod presented specimens of (a) "Diverticulum of the Fallopian Tube," (b) "Tuberculous Ulcer of the Tongue," (c) "Sarcoma from the Back of a Patient Sixty-six Years Old." Dr. Randle C. Rosenberger presented a communication entitled "Homogenized Cultures of Tubercle-bacilli." He described the variations in morphology observed under such conditions, and stated that he had been unable to detect motility. Dr. D. H. Bergey read a paper entitled "The Influence of Pasteurization on the Chemical and Physical Qualities of Milk." He had found that milk heated for 15 or 20 minutes to a temperature of 68° C. had its content of lactic-acid bacilli largely diminished, while those of the subtilis group persisted in undiminished if not increased number. Although such milk became sour less readily it acquired a disagreeable odor. Dr. M. E. Pennington read a paper entitled "A Comparison of Pasteurized and Raw Milk." She described the conditions found in a number of pasteurizing plants in Philadelphia, and pointed out how different the conditions present in many of these are from those found in the laboratory in which the process of pasteurization is carried out. Bacteriological examinations showed that while pasteurized milk contained fewer bacteria at the outset than untreated milk, microorganisms multiplied far more rapidly in the former than in the latter when of reasonable purity. Dr. J. Evans and Dr. Cope presented a communication entitled "Does Milk Possess Germicidal Properties?" Some observations that they had made seemed to answer this question in the negative, certain microorganisms apparently exerting an antagonistic influence upon others. In the discussion Dr. A. C. Abbott stated that the only conclusion to be drawn from the evidence in the case was that pasteurized milk is not to be commended as an article of food for children, but that much more is to be accomplished by taking steps to secure a supply of milk in as high a state of purity as possible. Dr. D. L. Edsall pointed out that milk subjected to pasteurization undergoes deleterious changes affecting not only its physical and chemical qualities, but also its digestive and nutritive properties. Dr. C. A. Fife discussed at some length the chemical changes that take place in milk as a result of the process of pasteurization.

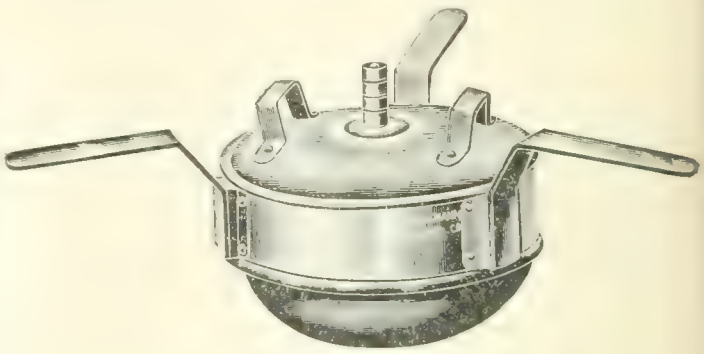
The Prophylaxis of Venereal Diseases.—Dr. Prince A. Morrow, writing in the *Journal of the American Medical Association* for March 4, says that the extent of venereal diseases in married life is far greater than is commonly supposed. The chief social danger comes from the destructive effects on the health and on the productive energy of the family. Regulation of prostitution according to the European methods he considers practically ineffective, as it applies only to one sex. We might as well attempt to prevent the importation of plague by excluding only the infected women. The method of prophylaxis in which he puts the most confidence is education, both of youths and of the public generally. The public conscience must be awakened. The present indifference, based on ignorance, and the popular notion that these diseases are simply consequences of vice, must be done away with. In his opinion, a special society, including in its membership educators, clergy, jurists, and sociologists, as well as medical men and public-spirited individuals generally, should undertake this work. It should be a permanent organization, exerting a continuous active force against this prevalent evil. He believes that with organized and intelligent effort many of the apparently insurmountable difficulties of this question eventually may be overcome.

A NEW STOOL SIEVE AND ITS METHOD OF USE.

By DUDLEY D. ROBERTS, M.D.,

BROOKLYN, N. Y.

The writer, having found the various forms of stool-sieve, previously described, very impracticable for office use, has had one constructed that he has found very satisfactory. The lower part of the apparatus, as shown in the cut, is a two-and-a-half-inch band of tinned copper, to the bottom of which copper sieve No. 40 or 60 is fastened in the form of a bowl. This part is suspended in the bowl of the water-closet by the three arms, and the seat is then shut down, that the patient may comfortably defecate directly into the sieve. To catch complete portions of thin



stools, a bowled copper plate may be placed over the sieve. The lid has a perforated plate on its under side which distributes the water in fine streams over the specimen. A rubber pipe is fastened to the pipe seen projecting through the lid, and water is thus conveyed from a nearby faucet. For greater convenience the water can be obtained from a faucet introduced in the water pipe leading to the water-closet tank. This is a matter of small cost, and has no detrimental effect on the supply to the tank.

When the apparatus is used the stools leave no objectionable odor about the office laboratory, as is the case when other forms of stool sieve are employed. It is also an advantage to have the dejections received directly in this manner, saving transportation by the patient and transference from one vessel to another by the examiner. The cleansing of the sieve is rendered easy by detaching the supporting arms and placing it inverted in the water-closet bowl so that a stream of water may be directly applied.

84 Remsen Street.

The Clinical Effects of Surgical Anesthesia and Operations Upon Anemic Patients.—Henry T. Hutchins gives the following summary of his investigations: Sixty women, each showing a hemoglobin percentage of 50 or less, have received a general anesthetic for operative purposes, the duration of the anesthesia varying from 20 minutes to 3½ hours. The anesthetic used was ether alone or the nitrous-oxide-ether sequence in every case but one, none of the patients having received chloroform. Fifty-six of the sixty cases had uneventful recoveries. There were four fatalities. Severe heart lesions complicated two of these; in the third the patient had already bled till her hemoglobin registered 15 per cent., and in the fourth case the anesthetic had been given for 2½ hours before the patient showed any signs of immediate collapse. Two cases only died on the table under the anesthetic. The worst shocked patient of all had a hemoglobin percentage of 50; her operation was an ordinary suspension of the uterus and repair of relaxed vaginal outlet, an hour and seven minutes being consumed by the operations. The patients as a rule have taken the anesthetic well. There has been no respiratory distress noted, and in neither of the cases dying on the table was respiratory failure primarily the cause of death. Recovery from the anesthetic and the following convalescence was satisfactory in a great majority of cases. In no case was it thought that the persistence of the anemia after operation was in any way prolonged by the giving of the anesthetic. Preliminary tonic treatment proved of value in raising the hemoglobin percentage in the six cases in which it was tried.—*Bulletin of the Johns Hopkins Hospital.*

Books Received.

Studies in General Physiology. By Jacques Loeb. The Decennial Publications, Second Series, Vol. XV., Parts 1 and 2. 8vo, 1-422 and 423-782 pages, illustrated, muslin. The University of Chicago Press, Chicago. Price, $7.50 net.

The Treatment of Nervous Diseases. By Dr. J. J. Graham Brown, F.R.C.P.E., F.R.S.E. 8vo, 464 pages, muslin. William Green & Sons, Edinburgh and London.

Lehrbuch der Speciellen Chirurgie für Aerzte und Studierende. Von Dr. Franz Koenig. Eighth Edition, Volume 3. 8vo, 972 pages, illustrated, paper. August Hirschwald, Berlin.

The Opthalmic Year-Book. A Digest of the Literature of Opthalmology, with Index of Publications for the Year 1903. By Dr. Edward Jackson, A.M. 8vo, 260 pages, illustrated, muslin. The Herrick Book and Stationery Co., Denver, Colo., 1904.

The Effect of Tropical Light on White Men. By Major Chas. E. Woodruff, A.M., M.D. 8vo, 358 pages, muslin. Rebman Company, New York.

The Life of Florence Nightingale. By Sarah A. Tooley. 8vo, 344 pages, illustrated, muslin. The Macmillan Company, New York.

A Treatise on Urological and Venereal Diseases. By Dr. Bukk G. Carleton. 8vo, 795 pages, illustrated, muslin. Boericke & Tafel, Philadelphia. Price, $5.00

The Modern Mastoid Operation. By Dr. Frederick Whiting, A.M. 4to, 353 pages, illustrated, three-quarter morocco. P. Blakiston's Son & Co., Philadelphia. Price, $6.00 net.

Treatment of Tetanus by Epidural Injections of Antitetanic Serum.—G. Mornac reports a case of tetanus treated by epidural injections of antitetanic serum. Although the patient died, the writer believes that the rapid course of the intoxication and the tardiness of intervention were to blame for the fatality. Instead of discouraging the continuance of this treatment, the history of this case should be only an impetus to the application of this method in new cases that are presented. But the treatment should be given in the early stages of the disease. The writer declares that it is his profound conviction that further trials will demonstrate that the epidural injection is an easy and rational method, and is superior to all others when the portal of entry of the microorganism is a wound of the lower extremities.—*La Presse Médicale*, February 11, 1905.

The Treatment of Chronic Renal Disease.—Sir John W. Moore gives as the prime causes in the production of chronic parenchymatous nephritis, intemperance and exposure to cold and wet. The cases of chronic interstitial nephritis are usually the result of chronic plumbism in house painters and plumbers, while alcoholism also plays its part. Treatment of chronic kidney disease should proceed on three main lines, viz., dietetic, eliminative, and cardiac. The kidneys should be kept flushed by soft water. Nitrogenous food should be given sparingly, but the patient must not be allowed to suffer the pangs of starvation or waste for want of it. Milk is well borne in most cases, as are the lighter animal broths. When patients dislike a "slop-diet," white meats and white fish may be allowed. Copious draughts of soft water will assist elimination through the kidneys. Special attention must also be paid to the skin, bowels, and lungs. The open air treatment is indispensable in dealing effectively with chronic renal disease. Overexertion should be avoided, however.

The physical state of the heart and circulation is the paramount factor in the prognosis of chronic renal disease. The indications for treatment are to strengthen and aid the left ventricle in its work, to relieve tension in the right ventricle, and to bring high arterial tension down toward the normal. Digitalis is the best cardiac tonic. If an iodide is given with it, the objection of increased arterial tension caused by the digitalis alone may be met. If the drug is given with effervescent citrate of caffeine, it will not nauseate. A full dose of a saline laxative will relieve the pressure on the right ventricle. Arterial tension, if very high, must be gradually reduced by laxatives, the various nitrites, the iodides, and a restricted diet. The writer speaks, in closing, of the administration of macerated pork kidneys. Excellent results have been claimed for this method of treatment, but the writer has had no very definite or satisfactory experience with it. He urges physicians never to despair in a case of chronic nephritis, for recovery is not impossible.—*The Dublin Journal of Medical Science.*

The Occurrence of Myelocytes.—Schindler has made a large series of blood counts in different infectious diseases, and finds that myelocytes are to be found in the circulation in many common maladies. Among these are pneumonia, scarlatina, diphtheria, erysipelas, meningitis, polyarthritis, and general sepsis. The presence of these cells in the circulating blood may be of great or little import, according to circumstances. A few myelocytes appearing at the height of a leucocytosis, and disappearing together with its subsidence, have little significance, and indicate simply temporary overactivity of the bone marrow. The myelocytes give an unfavorable prognosis, however, when they are found in the blood of patients whose leucocytosis is diminishing, while the infection is continuing with unabated violence, as in this case the bone marrow is evidently becoming exhausted in consequence of the demands that have been made upon it.—*Zeitschrift f. Klinische Medicin.*

Treatment of Certain Dermatoses by Radium.—Danlos, after having employed radium in the treatment of a series of cutaneous lesions, reports the results of his experience. Up to the present time, he states, radium has been truly successful in three affections only: lupus vulgaris, pearly epithelioma, and the vascular nævus. Besides, this treatment is of indubitable value only in limited forms of these affections. For extensive lesions, it is in reality inferior to the *x*-ray, which is more easily applied to a large surface. Its use is preferable in certain cavities (the larynx and nasal fossæ) because they are not easily accessible to the *x*-ray. It can be said, then, in a word, that if perhaps the future is for radium, the present is without doubt for the *x*-ray. Jacquet adds that the new methods of treatment, radiotherapy and phototherapy, are excellent, and often give marvelous results, but on this account the older methods ought not to be scorned, for they in their turn gave good results.—*Gazette des Hopitaux Civils et Militaires,* February 14, 1905.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the period from February 26 to March 3, 1905:

ASSOCIATE SURGEON TO HOSPITAL FOR RUPTURED AND CRIPPLED.
NEW YORK.

From 1890 to 1904 there were treated in the outpatient department of the Hospital for Ruptured and Crippled, 53,686 patients with inguinal and femoral hernia. Of these 50,961 were inguinal and 2,725 femoral. More than one-third of these patients, 15,375, were children under the age of 14 years.

From December, 1891, to October, 1904, 1,500 operations have been performed at the Hospital for Ruptured and Crippled for the radical cure of hernia. With the exception of 20 operations, all have been in children under the age of 14 years. The fact that these cases have been selected from more than 15,000 under treatment during this period, is sufficient evidence that we have not operated indiscriminately upon all cases. The operative cases represent the worst cases of rupture, the largest, and those of longest duration, and in most instances a truss had been tried and failed.

It has been our custom to treat all our cases of hernia in children, with certain exceptions to be noted, for a period—usually one or two years—with a truss, before advising operation. If at the end of this period no improvement is observed and the rupture frequently comes down, an operation is advised. The operation is advised, furthermore, when the following conditions exist, without any reference to truss treatment:

1. Cases of strangulated hernia, or cases in which strangulation has occurred or reduction has been effected by taxis.
2. Cases of hernia with reducible hydrocele, or fluid in the hernial sac.
3. Cases of irreducible hernia (rare in children).
4. Cases of femoral hernia, which are practically incurable by truss treatment.

In cases under four years of age we seldom advocate operation, since the chances of a cure by truss treatment are far greater in young infants.

The question of how large a percentage of cases of hernia in children can be cured by mechanical means, is a most important one. When we began operating for hernia in children, in 1890, at the Hospital for Ruptured and Crippled, it was frequently stated that all cases of hernia in children could be cured by truss treatment. The falsity of this assumption is shown by the fact that in a study of 15,000 cases of hernia in adults, a large percentage gave a history of hernia in infancy or childhood. It is also highly probable that many more cases really had a hernia during infancy, which was apparently cured by a truss and the existence of which they had long forgotten. At present many surgeons advise operation upon infants without trial of truss treatment.

Personally we believe that under the age of four years a very considerable number of cases of inguinal hernia and nearly all cases of umbilical hernia can be cured by truss treatment. Hence the advisability of giving mechanical treatment a fair trial before resorting to operation.

Corner,[1] in his recent lecture on the pathology and treatment of hernia in children, states that he believes that cases of hernia in infants and children that are cured by truss are practically always of the acquired variety, and he doubts if a case of congenital hernia is ever cured by truss. If this be true, it is most important to know the relative proportion of cases of hernia in children that are acquired and that are congenital. In our own series of 1,500 operations we have made a special effort to settle this point.

In 709 cases of inguinal hernia, in the male, in children operated upon at the Hospital for Ruptured and Crippled, the history definitely states the type of the sac. A congenital sac, *i. e.* a sac communicating with the tunica vaginalis, was found in 284 cases, while in 425 cases the sac was of the acquired type, having no communication with the tunica vaginalis. This is directly contrary to the opinion held by most surgical writers, but up to the present time there have been no statistics of hernia in children sufficiently large to determine this point. It is probable that in the great majority of cases of so called acquired sac, there is a preformed sac, existing since birth, though not communicating with the abdominal cavity.

The results of operation having proven that the question of mortality has been practically eliminated and that results are so uniformly successful, we have of late adopted the plan of advising operation in most cases of hernia in children past the age of four years, unless the hernia is very small. This is especially true in dispensary cases in which it is very difficult to get the truss properly looked after at home, to say nothing of the trouble and expense of the parents in bringing a child from a distant part of the city to the dispensary regularly for the one or two years necessary to effect a cure.

In deciding the question of operation in children, it is important that we should know the proportion of cases curable by truss treatment. This is a very difficult problem to settle, (1) because the children so easily drift away; (2) because no one, thus far, has taken the same trouble and pains to trace the

*Read at the meeting of the New York State Medical Association, October, 1904.

cures from truss treatment, that have been taken in following up cases of radical cure.

Our own experience shows that many cases give a history of relapse after apparent cure with a truss. In spite of this, it is but fair to state that about two-thirds of infants under the age of two or three years are apparently cured by truss treatment. After four years of age the curative value of a truss is much diminished, and the time required to effect a cure, much increased.

Of the 1,500 operations for different varieties of hernia that have been performed at the Hospital for Ruptured and Crippled during the period mentioned,* 1,435 were for inguinal hernia, 39 for femoral, 13 for umbilical, 8 for ventral, 2 for congenital hernia of the umbilical cord, 2 for epigastric, and 1 for lumbar hernia. Of this number, 13 were strangulated and 1,487 were not strangulated.

There is a general impression among surgeons, that the radical cure of hernia in children is a far simpler affair than in adults, and the opinion is freely expressed that good results can be obtained in children by almost any method.

Our own results in children, though a trifle superior, differ but little from those obtained in adults operated upon by the same method. We believe that operation in children is more difficult than in adults, although if skilfully done by a proper method, it may yield as good or even better results than in adults. In children the hernial sac is as thin as tissue paper, and to avoid tearing the sac or injuring the slender cord, requires far more delicate dissection than in the adult. The results of operation in children obtained by the methods in vogue prior to the introduction of Bassini's operation, were even more unfavorable than in adults, as is shown by 20 cases in children operated upon at the Hospital for Ruptured and Crippled prior to 1890 by the methods of Socin and Czerny, 50 per cent. of which relapsed within less than one year after operation. At the Johns Hopkins Hospital, of six operations for hernia in children performed by McBurney's method, two (33 per cent.) were followed by relapse.

The writers, who believe that any method will suffice to effect a radical cure in children, have, as a rule, operated upon, or observed, but few cases. Hilgreiner, who has recently published the results of 828 operations for hernia at Wolfler's Clinic at Prague, reports only 50 cases in children, and of these only 14 were traced beyond one year.

Inguinal Hernia in the Female (251 operations in 217 patients).—The methods employed in our operations for inguinal hernia in the female, have been practically identical with Bassini's in the male, barring the transplantation of the cord. The sac is first dissected from the round ligament well beyond its neck, a step which is somewhat more difficult than the separation of the sac from the cord in the male. Then the round ligament is allowed to drop back into the lower angle of the wound, beneath the deeper layer of sutures. In a small number of cases, one of the writers has excised the round ligament along with the sac. The wound is closed in three layers with kangaroo tendon, exactly as in inguinal hernia in the male. Thus far not a single relapse has been observed following these 251 operations.

These results, while they go far to prove that it is not necessary to transplant the round ligament in operations for the radical cure of hernia in the female, by no means prove the uselessness of transplanting the cord in the male, for the reason that the cord is considerably larger than the round ligament, particularly just above the symphysis pubis, where it emerges from the external ring.

Methods of Operation.—*Inguinal Hernia.*—The great majority of operations for inguinal hernia were performed according to Bassini's method, with the substitution of absorbable suture, namely, kangaroo tendon, for silk, used by Bassini. In addition to this, in most cases an extra suture was placed above the cord to prevent any widening of the new internal ring in an upward direction. The technique in brief is as follows:

After the sac has been tied off well beyond the neck at a point where it has begun to widen out into the general peritoneal cavity, the deep layer of sutures are placed as follows: With a small tape the cord is held up, and the first suture is placed so that it just touches the lower border of the cord when the latter is brought vertically to the plane of the abdomen; three to four more through the internal oblique and Poupart's ligament will suffice to close the canal to the symphysis pubis. Then the suture above the cord (Fig. 1) is inserted. The incision in the aponeurosis is then closed from above downward by a small continuous suture of kangaroo tendon, and the skin with catgut. No drainage is used, and the wound is dressed very carefully with sterile dry gauze and cotton and a spica bandage. A plaster spica is used in children under 14 years of age. The wound is dressed on the seventh day, and the patients are kept in bed two weeks, and allowed to go out in two and a half to three weeks, wearing a muslin spica bandage until four weeks have elapsed, after which time no support is worn.

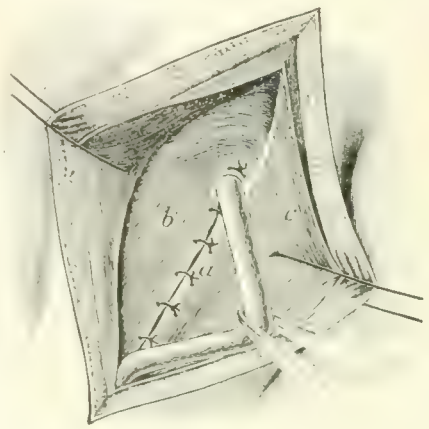

Fig. 1.—Bassini's operation (deep sutures) showing extra suture above the cord (Coley).

As early as 1892, we employed in a limited number of cases a method identical with Bassini's, without the step of transplanting the cord. Since this time 125 cases have been operated upon by this method at the Hospital for Ruptured and Crippled. In many cases of double hernia, the typical Bassini operation was done on one side, and the same operation without the transplantation of the cord, on the other, in order to fairly test the value of the two procedures. This method has been recently brought out under various names and has been advocated as superior to Bassini's method. In our own experience there has been a larger percentage of recurrences in the cases in which the cord was not transplanted, than in those in which the typical Bassini method was employed. However, the relative number of cases operated upon by the two methods has been too unequal to warrant a fair comparison.

In the present series of cases we have never ex-

* Of these 1,500 operations, Dr. Bull performed 270, Dr. Coley 815, Dr. Walker 361, and the assistant surgeons 54, of which Dr. Bullard performed 37 and Dr. Satterwhite 12.

cised any of the veins of the cord, and the results would seem to prove that such a step, considered of much importance by some operators, is unnecessary, at least in children.

In our operations upon adults we have likewise refrained from excising the veins, with almost equally good results as regards freedom from relapse.

If the cord is transplanted outside of the aponeurosis of the external oblique, according to Halsted's original method, in which the internal ring is protected only by the superficial fascia and the skin, it is quite evident that a recurrence would be less likely to occur with the cord reduced to a minimum size by excision of the veins. This seems to have been proved by Bloodgood's statistics of the operations at the Johns Hopkins Hospital. When, however, the cord is transplanted according to the Bassini method, in which, in addition to the skin and superficial fascia, the strong fascia of the aponeurosis of the external oblique serve as protection for the internal ring; the need for excision of the veins is not so apparent. Furthermore, the atrophy of the testis, which has been noted by many observers after excision of the veins, would seem sufficient reason for not adopting this procedure, provided equally good results can be obtained without it.

In 125 cases the cord was not transplanted, but was brought out at the lower angle of the wound. The other steps of the operation were the same as those in Bassini's method, with the exception that in two of the earliest cases, in 1891, the Czerny method was used, and the aponeurosis of the external oblique was not cut. This method, that is, the Bassini method without the transplantation of the cord, has been so strongly advocated in recent years, and is at present believed by so many to be equal to the typical Bassini method, that a comparison of our results following the two methods in children will be of interest. This method is known in Germany as Woelfler's operation without the "Verlagerung," or transplantation of the rectus muscle, but the earliest cases reported by Woelfler himself, at the Prague Clinic (vide Hilgenreiner[2]) were of 1895. In America it has been frequently called the Ferguson method, and was described by Ferguson in 1899. Yet the first cases in which one of the writers employed this method at the Hospital for Ruptured and Crippled occurred in 1892, and were reported in the *Annals of Surgery* for April, 1895.

Femoral Hernia.—Femoral hernia is said to be very rare in children, yet we have operated upon 39 cases of femoral hernia at the Hospital for Ruptured and Crippled, of which 28 were in children under the age of 14, and one, a double one, occurred in a child two years of age. Of 2,179 cases of femoral hernia observed at the Hospital for Ruptured and Crippled since 1890, 69 occurred in children under 14 years of age, or a little over three per cent. In one case, a girl of seven, there was a right femoral hernia and a double inguinal. All were operated upon at the same time, and there has been no recurrence after five years. Thirteen cases were in children under the age of ten years.

The method employed in most cases has been that of high ligation of the hernial sac, with a purse-string suture of kangaroo tendon, bringing the floor of the canal in contact with the roof.

There has not been a single relapse observed up to the present time, and thirteen cases have been traced for from two to eight years.

The technique of the so-called "purse-string method," as employed in our own cases, is briefly as follows: Thorough freeing of the sac well beyond the neck; high ligation of the sac and closure of the canal by means of a purse-string suture of chromicized kangaroo tendon. The suture is introduced through Poupart's ligament or the inner portion of the roof of the canal, or crural arch, from where it passes downward into the pectineal muscle, or floor of the canal, then outward through the fascia lata overlying the femoral vein and upward through Poupart's ligament or roof of the canal, emerging about one-fourth of an inch from the point of introduction. On tying the suture, the floor of the canal is brought into apposition with the roof, and the femoral opening is completely obliterated. The superficial fascia may then be closed with catgut or fine tendon, and the skin either with catgut or silk. This method of closing the femoral canal is much simpler than Bassini's, and, from the results obtained, we are inclined to give it the preference. The idea of closing the femoral canal by a purse-string suture was, we believe, originally suggested by Cushing of Boston, but his method of introducing it differs considerably from our own.

We believe it of utmost importance, in all operations for femoral hernia, to thoroughly free the canal of all extraperitoneal fat.

As regards the period of convalescence, the time is generally somewhat shorter than in inguinal hernia. Patients are usually allowed to sit up on the tenth day, and to go home at the end of the twelfth or fourteenth day.

Hernia of Cecum, Cecum and Appendix, Appendix and Sigmoid.—In 34 cases the cecum, or appendix, or both, were found in the hernial sac. In 12 cases the cecum was found alone, and in 8 of these cases the hernia was of the "sliding" type, or hernia

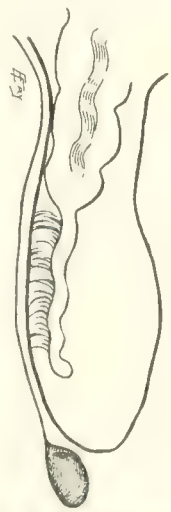

Fig. 2.—Hernia of the Cecum and Appendix.

Fig. 3.—Sliding Hernia of the Cecum.

"par glissement" of the French writers, with no posterior wall to the sac. In nine cases the appendix was found alone in the sac, and in one case, a boy of seven years, a large appendix was found adherent to the sac of a large inguinal hernia. In thirteen cases the cecum and appendix were both found in

the sac, and in three of these instances operation was performed for strangulation.

In most cases the appendix was removed when found, especially if adherent, and while at first we had some doubts about the advisability of removing a normal appendix when found in a hernial sac, we now believe it wise to do this. It adds little to the gravity of the operation, and avoids the possibility of a future attack of appendicitis.

There were two cases of sigmoid hernia, one of them strangulated. Sigmoid hernia is very rare in children.

The operation for the radical cure of cecal or sigmoid hernia differs in no respect from ordinary technique, except in the case of sliding hernia. Here we have an entirely new problem, and not an easy

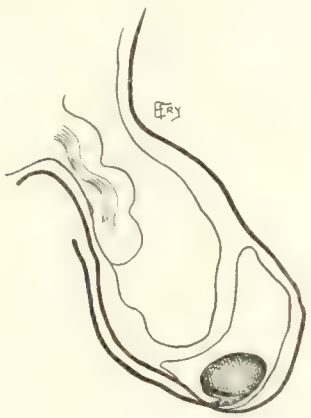

Fig. 4.—Sliding Hernia of the Cecum with Hydrocele of the Tunica Vaginalis.

one to solve. Instead of a sac, the contents of which can be entirely reduced and the neck of the sac closed high up, we have only a partial sac, the anterior portion consisting of the usual peritoneal layers, but the posterior portion made up of the cecum itself, which has slid downward into the canal or scrotum. We may separate the cecum from the tissues behind it and force it upwards for a short distance, but having no "neck of the sac" to close, as in ordinary cases, it is far more difficult to prevent a relapse.

In our own eight cases of sliding cecal hernia there has been but one relapse, and in this case the operation was done for a relapse following a primary operation at another hospital. The original wound had healed by granulation, and the second operation was difficult and prolonged.

The method we have employed in these cases has been to free the cecum as thoroughly as possible, suture the upper portion of the sac, and close the canal by Bassini's method, with or without the transplantation of the cord.

Of the 34 cases observed, 13 occurred in patients under the age of five years, 3 occurred in patients under the age of one year. (In these three cases the operation was done for strangulation.) Only one case was observed between the ages of 10 and 14 years.

Hernia Associated with Undescended Testis.—In 85 cases an undescended or partially descended testis complicated the operation. The proper treatment of this condition has not yet been authoritatively settled, on account of absence of sufficient data. No single operator except Broca has reported more than a small series of cases, the after-history of which has been imperfectly traced.

While some surgeons advocate truss treatment in all cases of undescended testis with hernia, in children, and others advise operation in every case, even in infants, we have taken a middle ground. Our experience with truss treatment in a very large number of cases has proved very unsatisfactory. Nature's efforts to force the testis out of the canal are thwarted, and the more or less constant pressure of the testis in this canal, prevents any cure of the hernia. The objection so often mentioned, viz., the danger of the truss causing malignant disease, sarcoma of the testis, from pressure, need not be considered.

Fig. 5.—Undescended Testis, with Double Obliteration of the Vaginal Process of the Peritoneum.

McAdam Eccles, in his elaborate study of the undescended testis, states that of 48,000 cases of hernia, with 854 cases of undescended testis, not a single example of malignant disease was noted, and this opinion is confirmed by our own experience, based upon the observation of over 60,000 cases of hernia treated at the Hospital for Ruptured and Crippled since 1890.

We have thus far advised against operation in infants and young children up to the age of eight or ten years, unless the hernia was of large size, the reason for this being that the testis often descends of itself if left alone and no truss is applied. The rupture is not likely to become strangulated, as the testis prevents the intestine from getting outside the external ring, which we have shown to be the cause of strangulation in children. Inasmuch as an operation to cure the hernia is nearly always necessary, even after the testis has come down, we do not wait as long as formerly before operating. If the testis is outside of or can be forced outside of the external ring, we can usually free the cord sufficiently to permit bringing it down into the scrotum by operation.

In our early cases we attempted to anchor the testis either to the scrotum or to metal frames outside of the scrotum, but we soon abandoned such attempts, as the testis almost invariably retracted to the region of the external ring. Originally Bassini's method was employed, but in recent years we have given up transplanting the cord, thereby gaining an appreciable lengthening of the cord and securing the testis a lower position in the scrotum.

While it is of great importance to free the cord thoroughly, sacrificing some of the veins, if need be, and cutting away the fascia about the veins, we think the step advised by Bevan, of separating the veins high up in the iliac fossa by blunt dissection with the index finger, likely to be attended with some risk of severe hemorrhage. It is very important to so close the tissue at the external ring that the testis cannot re-enter the canal, even if it should retract thus far.

While we have not observed any case of relapse of the hernia in this series of cases, in a considerable number of cases, especially the earlier ones, the testis has retracted to the external ring, when it was removed without giving rise to any trouble. In some cases the testis has gone on developing in size and has remained in the scrotum, differing little from the normal testicle. In the majority of cases it has remained more or less atrophied, and the question of removing the undescended testis in operations for the radical cure of hernia is still unsettled.

We have always believed it wise to preserve the

organ, even if it should never develop to be of functional value, and the careful investigations of Eccles and others go far to prove that a testis, though it be of no functional value, may have great influence upon the development of the child, especially as to points pertaining to characteristics of sex.

Direct Hernia in Children.—We have not observed a single case of direct hernia in children.

Interstitial Hernia.—Of the rarest variety, properitoneal hernia proper, in which the sac lies beneath the transversalis fascia, no case has been observed; of the other two varieties, first, the most common, viz., in which the sac lies directly beneath the aponeurosis of the external oblique, we have seen 77 cases. In this class we have to include most of the cases of hernia associated with undescended testis. Of the third variety, "inguino-superficial," as styled by the German writers, we have operated upon seven cases in children. In this class of cases the sac, after emerging from the external ring, passes upward and rests upon the outer surface of the external oblique, aponeurosis. We believe it to be much more common than is generally supposed. Moschcowitz[3] states that only seventeen cases have been reported. One of the writers has operated upon ten cases, including adults.

Strangulated Hernia in Children.—Thirteen operations were performed for strangulated hernia upon children between the ages of 13 days and 15 years. Five patients were under the age of one year and seven under the age of two years. There was only one case of strangulation between the ages of 3½ years and 14 years, showing that strangulation is much more common during the first two years of life than during the next decade. In one case, in a boy of 15, the strangulation was a partial enterocele, or Richter's variety.

The duration of the strangulation ranged between 12 and 48 hours.

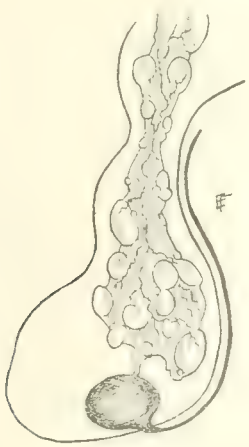

Fig. 6.—Multiple Cysts of the Omentum.

There was no mortality in the entire series of thirteen cases, though in two cases recovery was not expected. In one case a temperature of 107°, with a pulse rate of 180, developed shortly after operation in an infant eight months old. This high temperature persisted through most of the following day, and the child was kept in a continuous bath of water at a temperature of 98°. The child made an uninterrupted recovery, and the wound healed per primam, as was the case in all of the other patients.

Most writers upon strangulated hernia in infants have stated that the neck of the sac was the cause of the strangulation in the majority of the cases. Our series of cases showed in every instance that the strangulation was the result of constriction by the tight external ring, and as soon as the aponeurosis of the external oblique had been divided there was no difficulty in reducing the hernia. The error in attributing the strangulation to the neck of the sac is probably due to the fact that in the earlier cases of hernia in infants there was little attempt at careful dissection, and seldom any effort made to effect a radical cure. The sac and aponeurosis were simply divided at the same time, and it is not surprising that the mistake should have occurred.

Fig. 7.—Hernia of the Tube and Ovary Adherent to the Sac. (Two cases observed by the writers.)

While fecal impaction was regarded by the ancient writers as one of the important factors in the production of strangulated hernia, most modern authorities believe it has no casual relationship. In one of our cases fecal impaction was apparently the chief cause of the strangulation.

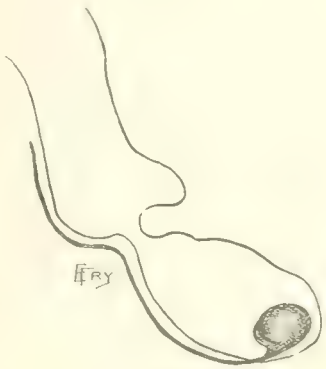

Fig. 8.—Hourglass Sac.

Tuberculous Hernia, or Tuberculosis of the Hernial Sac.—We have observed two cases of tuberculosis of the hernial sac in children at the Hospital for Ruptured and Crippled; the writers have furthermore observed two cases in adults, one a femoral and one an inguinal hernia.

The subject has recently been treated by Sacquépée and Melliés[4]. These authors report two cases, both in adults, in one of which the diagnosis was confirmed by microscopical examination. They were able to collect from medical literature 52 cases. In 22 of these 52 cases the age of the patients was under ten years.

Of 39 cases operated upon, three died of the operation, two died during the first year of intestinal tuberculosis, and one two years later, of tuberculous meningitis. In several cases the patients were well three, four, and five years after operation.

Hilgenreiner[2] reports four cases of tuberculosis of the hernial sac in a series of 828 cases, or three in 770 patients operated upon. The condition is undoubtedly a rare one. Lewisohn was able to collect but 58 such cases from the literature, to which he added four of his own.

Umbilical, Ventral, and Epigastric Hernia.—Two cases of epigastric hernia, 10 cases of umbilical hernia, and 2 cases of ventral hernia, 2 cases of congenital hernia of the umbilical cord, 2 cases following operation for acute appendicitis, 2 cases of hernia of the tube and ovary were operated upon; also a

very rare case of multilocular cyst of the omentum and 1 case of lumbar hernia, were treated by operation. In the few cases of umbilical hernia in which operation was indicated we have found that closure of the wound in three layers, without any overlapping, has been sufficient to effect a cure. In the adult cases we believe that the method of overlapping, as described by Blake and Mayo, is probably the best.

Thus far we have observed no recurrence in this group of cases.

Practically all cases of umbilical hernia in children under the ages of 12-14 years may be cured by mechanical means.

The method we employ consists in applying a two-inch strip of zinc oxide rubber adhesive plaster, which entirely encircles the abdomen and holds in place a small pad, usually made of a wooden button mold, one inch in diameter and covered with adhesive plaster. This is changed once every one or two weeks. The period required for a cure varies with the size of the opening, but ordinary cases are cured in about a year.

Study of Relapsed Cases.—Of the 1,500 operations for the radical cure of hernia at the Hospital for Ruptured and Crippled since December, 1890, there have been six relapses after 1,076 Bassini's operation, and five in 125 in which the cord was not transplanted.

Relapses After Bassini's Operation.

Case I.—J. H., male, 6½ years old. Bassini's operation, substituting kangaroo tendon for silk in the buried sutures done in October, 1894. Primary wound healing. Slight relapse one year later.

Case II.—J. W., male, nine years old. Operated upon by Bassini's method in August, 1894. Slight relapse two years later. Truss applied for a time; then left off. Examination 1903, nine years later, shows only a slight impulse on coughing.

Case III.—B. B., aged six years. Right inguinal hernia. Operated upon June 12, 1903. Wound healed by primary union. On July 15 the patient had a severe attack of whooping cough, during which time he applied no support to the recently healed wound of the inguinal canal. A recurrence was noticed on August 8.

Case IV.—H. K., aged twelve years. Operation for right inguinal hernia, congenital type, Nov. 2, 1900. Bassini method. A slight relapse was noted in November, 1902, two years after operation.

Case V.—E. S., male, aged six years. Right inguinal hernia. Operation Nov., 1897. Bassini, kangaroo tendon. Relapse two months after operation.

Case VI.—W. F., male, aged 8 years. Left inguinal hernia. Operation, 1899. Bassini's method, kangaroo tendon; collodion dressing. Slight relapse. September, 1900, truss for a time. Examination June 2, 1903. Very slight protrusion; truss reapplied.

Relapses in Cases in which the Cord Was Not Transplanted.

Case I.—H. O., aged eight years. Operation Dec. 12, 1891. Cord not transplanted. Relapse three months after operation.

Case II.—C. R., thirteen years old. Very large right inguinal hernia. Operation Dec. 28, 1891; cord not transplanted; silk used for the deep buried sutures. Wound suppurated and most of the deep sutures came out. Relapse within three months after operation.

Case III.—B. S., aged twelve years. Right inguinal hernia. Operation Jan., 1892; cord not transplanted; silk used for the buried sutures. The wound healed by primary union, but a few weeks later a sinus formed, and a few silk sutures were extruded. Relapse followed a few months later. Patient was re-operated upon by Bassini's method and was entirely well ten years afterwards.

Case IV.—F. H., ten years of age. Operation in February, 1892; cord not transplanted; chromicized catgut for buried sutures. Patient remained well for three years, when a slight relapse occurred.

Case V.—E. B., aged six years. Operation February, 1901; cord not transplanted; sliding cecal hernia. Relapse three months after operation.

A closer study of these relapses is of some interest. It appears that in four of the five relapses following operation without transplantation of the cord the operation was performed in 1891-2, or more than twelve years ago. In two of these cases silk was used for the buried sutures, with subsequent sinus formation, which weakened the canal and was, undoubtedly, an important factor in causing the relapse. In the fifth case, which relapsed after operation in 1901, we had to deal with a sliding cecal hernia, a form of rupture a radical cure of which is admitted to be almost impossible of attainment with any method of operation. Still, five relapses in a series of 125 cases in which the cord was not transplanted is certainly a much higher percentage than that in the cases in which the cord was transplanted.

Coming to the cases of inguinal hernia operated upon by Bassini's method, with the substitution of kangaroo tendon for silk for the buried sutures, we have 1,311 operations, with six relapses. Two of these relapses were very slight, one of them showing only a moderate impulse on coughing nine years after operation, and one was due to a severe attack of whooping cough coming on four weeks after operation.

Further observations confirm us in the opinion that the majority of relapses after any operation for inguinal hernia occur during the first six months after operation, and about 90 per cent. of the entire number occur during the first year. This opinion is based upon 504 cases of relapses after radical cure operations observed in the out-patient department at the Hospital for Ruptured and Crippled during the past fourteen years, and recently collected by one of the writers. Of these 504 cases, 83 per cent. occurred during the first six months, and over 90 per cent. during the first year.

This opinion receives further support from a series of 145 cases collected and reported by Pott,[5] who found that 71.66 per cent. occurred during the first six months, and 91 per cent. during the first year.

Wound Healing.

The following table shows the number of cases that healed by primary union and with suppuration according to each year from 1891 to 1905:

Year.	No. of Cases.	Supp'r-ations.	Year;	No. of Cases.	Supp'r-ations.
1891	2	1	1899	129	4
1892	41	1	1900	149	3
1893	31	2	1901	153	8
1894	68	2	1902	128	3
1895	68	3	1903	210	1
1896	52	1	1904 (to March 3, 1905)	201	5
1897	73	7			
1898	99	6	14 years	1424	47

A careful bacteriological study of some fragments of skin taken from the field of operation just prior to the making of the incision was made by Dr. F.

M. Jeffries, the pathologist to the hospital, in 290 cases, with the following result:

Total number of skin cultures	290
Number of instances in which growth was obtained	27
Per cent. not sterile	9.31+
Streptococcus obtained, number of times	7
" " per cent.	2.41
" alone—number of times	4
" and a diplococcus—number of times	2
" " tetrad " "	1
Micrococcus tetragenous " "	10
A diplococcus	6
Tetrad and bacillus	1
Bacillus alone	2
Stapyhlococcus and a bacillus	1

Of the total number of 1,424 operations, suppuration occurred in only 47, or 3.3 per cent. Of these it was superficial and very slight in 35 cases, and involved the deep tissues in 12. The use of rubber cots for the operator and rubber gloves for the assistants was beung by one of the writers in December, 1899. In 1900 there were only two cases of suppuration in 149 operations. In one of these cases rubber cots were not worn by the operator or assistants, and in the other case, a portion of the skin removed from the operative field just before operation showed a pure culture of streptococcus. The day after the operation the temperature rose to 104°, pulse to 160. The wound was opened up and showed deep suppuration. Cultures made from the pus showed pure cultures of streptococcus, proving with little doubt that the infection was due to imperfect cleansing of the skin. In the following year, 1901, there were eight cases of suppuration; in five of these gloves were not worn; two of the cases were operated upon by the house surgeon, and, although rubber gloves were worn, the time of operation was prolonged nearly an hour, and there was much bruising of the tissues. The other case was operated upon by one of the writers, who wore gloves; the suppuration was slight and superficial. In 1902 there were three suppurations in 128 cases; in 1903 210 operations, with only one slight suppuration.

Dividing the cases into two periods, namely, before and after the introduction of rubber gloves as a routine measure, we find 567 cases operated upon before the use of rubber gloves, with suppuration in 25, or 4.4 per cent., and 933 operations performed since the use of rubber gloves, with suppuration in only 20 cases, or 2.1 per cent.

Suture Material.—The question of suture material for the buried sutures in the operation for the radical cure of hernia we regard as a most important one. We have since 1891 used an absorbable suture—kangaroo tendon—chromicized sufficiently to resist absorption for about four to six weeks. The disadvantages of using non-absorbable material, *e.g.* silk, silver wire, silkworm gut, for the buried sutures we have frequently and strongly emphasized. We have also shown by repeated observation at the Hospital for Ruptured and Crippled that buried non-absorbable sutures frequently cause abscesses, with the formation of sluggish sinuses, that usually persist until the offending sutures have been removed by the surgeon or extruded by nature. More than thirty such cases have come under our personal observation, and in most of these cases the original wound healed by primary union. In some instances the sinus did not develop until three years after operation. In the majority of these cases recurrence developed as a result of the long-continued suppuration, leaving a condition most difficult to treat by means of a truss, and one offering little prospect of a cure from further operation.

If any additional evidence were needed to prove that the use of buried non-absorbable sutures, especially in operations for the radical cure of hernia, has no sound basis from either a clinical or a pathological standpoint, we would refer to the statements made by Sir William Macewen,[6] in his recent address in Surgery, delivered before the British Medical Association in 1904. He says:

"At the present moment many investigators content themselves by aiming at a sterilized material for sutures and ligatures. Asepticity is by many considered a sole requirement of a ligature otherwise mechanically suitable, but asepticity is only one of the requirements; a further requirement which the ligature should possess is that it will remain in the tissues for a time sufficient to effect its purpose, and which will then be capable of rapid elimination. The same desiderata are for sutures.

A material capable of maintaining the tissues in contact sufficiently long to enable the tissues to proliferate and to effect a living union of the parts is required, and after this has been accomplished the suture material ought to become eliminated without disturbance of the parts, so that when the mission of the suture has been accomplished, it should no longer remain in the tissues, a useless, dead material, capable of producing irritation, but should permit itself to be speedily removed.

"Some surgeons have introduced wire sutures, in the belief that they would be able to bring together and maintain permanently in apposition tendinous and aponeurotic structures in inguinal hernia."

The futility of this latter hope may be judged from his own personal experience with five cases in which gold wire was used by other surgeons, and which subsequently came under his personal observation. Three of these cases came to him for a recurrence of the hernia, and in two cases for strangulation.

Our own experience furnishes cases almost as striking as those cited by Macewen. In one particular case, a patient 55 years of age, was operated upon in January. A sinus persisted until May, when a portion of the wire was removed. He continued to make almost daily visits to the outdoor department of a hospital until December, when the remaining sutures were removed, and by which time a well-marked recurrence had taken place which, in a few months, became several times as large as the original hernia; it was covered by thin cicatricial tissue, which made it absolutely impossible to wear a truss; furthermore, in such a condition as this, nothing whatever could be offered by another operation, and thus a man of 55 years, otherwise in good health, was incapacitated for the rest of his life for doing any manual labor, to say nothing of the pain and discomfort associated with such a condition.

If a careful report of the after-histories of all the cases in which non-absorbable sutures were used were made, we have no doubt the observations of Macewen and ourselves would be many times duplicated, and would go far in the direction of leading surgeons to abandon the use of such sutures in operations for the radical cure of hernia.

Mortality.—There were four deaths in this series of 1,500 operations, or a mortality less than 3-10 of one per cent. An analysis of the cases of deaths shows that:

Case I.—A child of eight years. Operation was done for right inguinal hernia in 1893. Patient died of double ether pneumonia on fourth day. Autopsy showed no trouble with wound.

Case II.—I. M., male, aged five years. Operated upon for left inguinal hernia Jan. 11, 1895. Cord was not found; the sac was large and friable, and

the time of the operation was much prolonged, more than an hour. A high temperature developed the same evening (104°) and pulse rose to 140. The wound was opened up the following day, but the patient grew rapidly worse, and died thirty-seven hours after operation. Autopsy showed pus in the peritoneal cavity and death to have been due to acute septic peritonitis.

Case III.—A. B., male, aged six years. Operation, 1895. Right inguinal hernia the size of an orange, not controlled by a truss, and complicated with cervical Pott's disease of the spine. The child's general condition was poor, and he took the ether very badly. The following day the temperature rose to 105°-106°, and the pulse was very rapid and feeble. The wound was opened up and drained on the third day. Some pus was found. The child gradually failed and died on the twelfth day. Autopsy showed pericarditis and apex pneumonia.

Case IV.—This case was not operated upon by the writers, but by one of the assistants, and as it was one of his early operations, the time of operation was somewhat prolonged. The patient, a boy aged six years, was operated upon June 13, 1903, for left inguinal hernia of moderate size. Bassini's method was employed, and rubber gloves were used by the assistants and operator. A high temperature developed the night following the operation and continued the next day. The wound was opened and an extensive filtration of the tissues found, with spreading cellulitis. In spite of free incision, irrigation and wet dressing, he continued to grow worse, and died on the fourth day of acute sepsis.

One of the writers has operated upon 800 consecutive cases without a single death.

One of the four deaths we have recorded was in a child much weakened by advanced Pott's disease of the spine, and in our present judgment operation should not have been attempted. The two deaths from acute sepsis we must class as theoretically preventable. One occurred before the use of rubber gloves, but in both cases the time of operation was nearly one hour, instead of the usual ten to fifteen minutes, and hence there was not only much greater chance for air infection, but the bruising of the tissues caused by the prolonged handling prepared a most favorable nidus for infection from any source.

Final Results.

Japanese Red Cross Hospital Ships.—A correspondent of *The Times* of London, gives an interesting account of the arrangements made by the Japanese Red Cross Society in the matter of hospital ships. The society has arranged to build its own ships to its own requirements, and to sell them to a steamship company with the proviso that they shall be at the service of the society when required, for a stated rental whilst in use. There are many other clauses in the scheme, which appears to be a practical one, and to have worked well.

ACNE AND ITS TREATMENT.*

By GEORGE T. JACKSON, M.D.,
NEW YORK.
INSTRUCTOR IN DERMATOLOGY IN THE MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY.

Acne is probably the most common of all diseases of the skin. It is true that statistics do not show this. According to them, eczema is the most common dermatosis. The reason for this is that the latter disease is very pruritic, and renders the patient so uncomfortable that he seeks medical advice; while a mild case of acne gives no discomfort, and a bad case is merely disfiguring. Unfortunately, there is an idea in the mind of the laity that nothing can be done for pimples, and that, anyway, the youth will grow out of them. I am sorry to say that this idea is encouraged by some physicians who have been unsuccessful in curing their acne cases. It is true that the disease is often very stubborn, and that relapses are frequently suffered, but the majority of cases can be greatly benefited in a short time, and very many of them cured promptly. One thing treatment does in all cases, it prevents the scarring that often occurs when the lesions are allowed to undergo evolution of themselves, or reduces it to a minimum. Moreover, even if treatment does not entirely cure, it certainly benefits, so that the patient is able to go into society without being an object of remark, or to obtain a position in the business or domestic world. That relapses occur is due to the frailty of man and the irksomeness of following out the rules for diet, exercise, and hygiene the physician is bound to lay down.

There is no need for me to describe the *clinical features* of acne. They are familiar to you. What I shall say applies to acne vulgaris alone, and not to other diseases to which the term acne has been applied, such as acne rosacea, acne frontalis, acne medicamentosa, and the like. The picture I want you to have before your mind's eye is the following: A young man or woman whose nose and forehead look and feel greasy, and whose face is studded over with comedones, white or red papules, small pustules alone, or interspersed with larger pustules, and dull red nodules. When the nodules are in large number the face feels lumpy. On the scalp there is usually a varying amount of dandruff. The same lesions that are seen on the face may also occur on the back, chest, and tops of the shoulders, and the skin over the breast bone and between the shoulder blades is often greasy to the sight and touch.

If we know *the cause* of a disease we are greatly helped in our efforts at curing it. So let us first try and discover the cause or causes of acne.

The great predisposing cause of acne is youth. In about eighty per cent. of my private cases the disease began between the fourteenth and sixteenth years. It is during this period that the skin, like the rest of the body, undergoes rapid development, and the sebaceous glands take on great activity, as shown by the greasy skin and the dandruff. I believe that this seborrheal condition is an essential predisposing cause of acne, and that it is very exceptional for acne to occur without it.

Errors of diet and hygiene are frequent in this period of life, having in their train digestive disorders and constipation, and, as a consequence, anemia, chlorosis, and the like. Young people are prone to eat too much or too fast, and to eat unwisely, all of which favor digestive disorders. I find these disorders in seventy per cent. of my private cases, constipation being the most common. These tend to

*Read at a meeting of the New York Academy of Medicine, February 16, 1905.

cause congestion of the skin of the face, impair its proper nutrition, and aggravate the seborrheal condition. Not only do they do this in youth, but also sometimes in later life, thus accounting in some measure for the persistence of acne into the third and fourth decade of life.

In women and girls menstrual disorders act in similar fashion, causing congestion of the face and increase of the seborrheal condition. I am convinced that their rôle in the production of acne is much less important than is generally supposed. In only eleven per cent. of my female patients were they noted, a proportion no greater, I believe, than would be found among a similar number of young women who had not acne. It must be borne in mind that the occasional "pimple" that in so many mature women is a forerunner of the menstrual period is not a true acne, but a purely local infection of the follicle mouth.

The importance of the seborrheal condition of the skin as the basis for the development of acne is shown by the fact that as it decreases, as it does about the twenty-second year of life, the acne tends to get well. There are certain skins that are peculiarly prone to acne. They are coarse in texture, with a multitude of wide open pores, evidences of a sluggishness in their vascular circulation. Such a skin is very greasy to the sight and touch, as it furnishes an excellent soil for infection by the microorganisms that are found in acne.

The exciting cause of acne is probably a microorganism. While I believe in the parasitic origin of acne, I speak of it as "probable" because it is not yet absolutely proven. The three leading exponents of the parasitic origin of acne are Sabouraud of Paris, Unna of Hamburg, and Gilchrist of Baltimore.

Sabouraud would explain the occurrence of acne as due primarily to the infection of the skin with the microbacillus which, when young, is punctiform and ovoid and less than 1-1,000 mm. in diameter. When full grown it is elongated, sigmoid, and resembles slightly the tubercle bacillus. These bacilli sometimes occur in chains. They form cocoons in the mouths of the follicles and stop them up, forming the comedones. When these become infected with the spores of Malassez or by staphylococcus albus we have acne lesions. The spores of Malassez he regards as the same as the bottle bacilli of Unna. They may be spherical in form, 2 μ to 7 μ in their long diameter, without mycelia, and occur discretely; or elongated or gourd shaped, with one spherical one upon another larger one; or budding, which are the spherical forms with buds. Whether the acne lesion is superficial or deep depends upon the depth to which the infection has gone.

Unna teaches that the acne bacillus is the cause of the disease, and describes it as from ⅝ to ¾ in its longest diameter.

Gilchrist believes that *Bacillus acnes*, discovered by him in 1899, is the cause of acne. He found it in smears from 240 pustules. In cultures taken from 145 lesions, 52 yielded pure cultures. It is a short, thick bacillus, in cultures becoming longer and thicker. The bacilli occur in groups, and in old cultures branching forms are seen. It is pathogenic in mice and guinea pigs. He states that to the naked eye a pure culture of Sabouraud's microbacillus looks like his (Gilchrist's) *Bacillus acnes*.

It seems hardly possible to escape the conclusion that acne vulgaris is of parasitic origin and due to a special form of microorganism. It would seem that Sabouraud and Gilchrist will soon be in accord, and that the bacillus acnes will be established as the exciting cause of acne. Besides the special microorganism, all observers have found the ordinary staphylococci in the pustular lesions of the disease.

That a special form of microorganism will produce acne between the ages of, say, twelve and twenty-four, and not before or afterwards, at first sight may seem opposed to the claim that it is the cause of the disease. Such action is not unique. It is a well-known clinical fact that ringworm of the scalp, which is due to the trichophyton fungus, and is a disease seen practically only in children, disappears of itself as the patient reaches the age of sixteen or seventeen. Some change, of a nature which escapes our knowledge, has taken place in the make-up of the scalp that renders it an unfit habitat for the fungus. And so it is in acne. When the skin has become fully developed, or the individual has attained to a certain degree of vigor, the microorganism no longer finds a proper soil for its growth. This matter of soil and infecting organism is now accepted in many diseases. It is probable that we have in our mouths more or less constantly pathogenic germs, that but wait some modification of the soil to produce disease. We therefore can easily accept the doctrine in acne. It seems to me that the parasitic theory of the origin of acne fits in with the facts better than any other theory does. The same disorders of digestion and assimilation that were supposed to be the causes of acne are met with constantly in the years after twenty-five and thirty, and are unattended by acne.

In the light of the etiology of acne as given above, we find out indications for *treatment* to be as follows: (1) Improve the condition of the skin, so that it will no longer be a suitable culture ground for the bacillus. (2) Empty the follicles of the skin of the colonies of bacilli. (3) Keep the skin constantly aseptic, so that any bacilli that escape on it will be killed, and no new infection of the skin will be possible.

The first indication, namely, to improve the condition of the skin, is met along the lines of general medicine. In taking charge of a patient with acne we should forget for the moment that there is any disease of the skin, and study him as a patient who is not in perfect health. Constipation, anemia, plethora, dyspepsia, lithemia, menstrual disorders, whichever or whatever we find must be relieved if we expect to effect a permanent cure of the disease. Diet, exercise, baths, attention to hygiene, and, lastly, drugs, are our means for combating the disorders we meet. There is no specific for acne. In most of the so-called "complexion cures" arsenic is the drug used. At times it may prove useful, but only in the very sluggish cases. In most cases it will do more harm than good.

The acne patient should keep good hours, take cold plunge baths if well borne, be out of doors as much as possible engaged in some active and agreeable exercise, and live on a plain, nutritious diet, without sweets or pastries, or foods fried in fat. The young man should forswear tobacco, and the young woman tight lacing.

The second indication, namely, to empty the follicles of the colonies of bacilli, is best met by the use of mechanical means. Three instruments are of service—the curette, the acne lancet, and the comedo expressor. If the number of acne lesions is great and the patient will permit, the most rapid way of meeting the indication is to put the skin on the stretch and go over it rough-shod with the curette, tearing off the tops of the pustules and comedones. After the curettage the face is to be bathed with a solution of boric acid, or bichloride of mercury, or peroxide of hydrogen, or the like. The curettage must be repeated two or three times a

week, tearing away the crusts from the previous operation and the tops of new lesions. No treatment is necessary between the operations excepting keeping the skin aseptic, as will be spoken of later. The curette should be a large, ring-shaped one, with

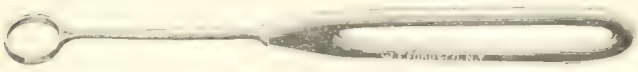

Fig. 1.—Curette.

dull edge. Reversed and pressed on the comedones, it forms an excellent comedo expressor. Before curettage, all deep lesions should be opened, as described later. Many patients object to this very vigorous method of treatment. For such, and for those who have only a few lesions, we should resort to the acne lancet and the comedo expressor. The

Fig. 2.—Acne Lancet.

acne lancet is an instrument triangular in shape, with two cutting edges and a shoulder above. Such an instrument can be rapidly plunged into the pustules, as the shoulder prevents its going too far in so as to do damage. It should always be used, and not an ordinary lancet, as it makes a clean incision that leaves no scar. I have seen some skins very badly damaged by the use of an ordinary lancet.

Comedo expressors are made of various shapes. The one I prefer resembles a cheese scoop, and has a rounded shoulder, so that it will not wound the skin. It is pressed steadily on one side of the

Fig. 3.—Comedo Expressor.

comedo, which will come out into the bowl. Before using it the skin should be softened by the application of warm water, with or without boric acid. Or the ring curette, reversed, as spoken of above, may be used.

After all the comedones are expressed, the acne lancet is used to open all the pustules. The contents of the pustules should be squeezed out after they have been opened. Deep lesions, the so-called indurated acne, which are small cutaneous abscesses, are to be opened and their contents squeezed out. This should be done even before they are "ripe." If they are squeezed between the fingers at this time one part of them will turn white, and it is into this point that the lancet is to be thrust. After they are opened, a little absorbent cotton should be wound on the sharpened end of a piece of wood, dipped in pure carbolic acid, and inserted into the cavity. This will prevent their refilling, which otherwise they are quite sure to do. After the face is gone over in this way it is to be washed off with some antiseptic solution, as after curettage. On the days between the operating days the skin should be rendered aseptic, as is described later.

Another method of meeting this indication is by pinching up the skin and rolling it between the thumb and fingers. I have often heard my friend, Dr. George H. Fox, compare this to working tacks out of a piece of leather. It is to be advised for patients who cannot be seen often enough for the other operations. I have not seen it spread the disease, as some say they have.

The third indication, to keep the skin aseptic, is met by the use of drugs. This form of treatment may be called the chemical method, to distinguish it from the former, or surgical method. The drugs may be exhibited in the form of lotions, ointments, and soaps. As we specially desire to free the skin of fat, which favors the infection, ointments do not seem to me to be proper vehicles, and I never use them. Moreover, they are not so agreeable to use as lotions. The chemicals that are of service in acne are sulphur, resorcin, mercury, and salicylic acid.

During my many years of experience in the treatment of acne I have tried many experiments, and have learned to place most reliance upon sulphur, and have found that the best way to use it is in the form of the old and tried Lotio Alba, the formula for which is: Zinc sulphate and potassium sulphuret, of each, ʒi-ii; rose water, q.s. ad. ʒiv. This is to be shaken up before using. It is rendered still more efficacious by the addition of a drachm or more of precipitated sulphur to the four ounces of the mixture.

Resorcin, twenty per cent. in water or alcohol, is often useful. It is to be dabbed on morning and night until it makes the skin red, dry, and glazed, as if varnished. Then the skin is to be bathed with an oxide of zinc lotion, or anointed with cold cream until the reaction subsides, after which the resorcin is to be used again.

A favorite preparation of mine that meets the indications is: Salicylic acid, gr. xl; calamine, gr. xx; zinc oxide, ʒss; glycerin, ʒii; lime water, ʒvi; rose water, ad. ʒiv. This, being about the color of the skin, can be kept constantly applied. Unless made by an expert chemist it is prone to become unusable in a few days, an insoluble salicylate of zinc being formed.

During more than a year I have used with the greatest satisfaction a soap containing sulphur, and known as Kreuznach Soap No. 2. This is made from the waters of the Kreuznach springs, in Germany, long celebrated in the treatment of certain diseases of the skin. It should first be used as an ordinary toilet soap night and morning, the lather being washed off. When the tolerance of the skin is ascertained the lather should be left on for a few hours in the evening, and later it should remain on all night. At first it smarts a good deal, but later it is well borne. Nothing has given me better results, either by itself or in combination with surgical methods, especially the latter.

So many trustworthy physicians have reported such excellent results from the use of the Röntgen rays in the treatment of acne, it would seem as if in them we had a most ready, rapid, and reliable cure of that disease. It seems to me that their use should be limited to intractable cases, especially as they occur in patients with sluggish skins, and to the disease as it occurs on the trunk. I have not yet met with a case of acne of the face in private practice in which I felt justified in recommending this treatment, because it is capable of doing harm. Not only may a most undesirable *x*-ray burn be produced, but careful operators have reported the production of an atrophic, abnormally dry and smooth skin. When they are used, it is advised that a moderately hard tube should be used; that the patient should be seated eight to ten inches from the target; that the exposures should last from three to six minutes, and that the sittings should be at intervals of three or four days for ten days to two weeks. No more than a slight erythema should be caused by the rays.

15 East Twenty-ninth Street.

Premature Death of a Would-be Suicide.—"Died while trying to commit suicide" was the verdict of a coroner's jury in London the other day and it was in accordance with the testimony. The excitement of getting a knife and preparing to kill herself was fatal to the would-be suicide, a despondent young woman, who had a weak heart.

THE LIMITATIONS OF THE VALUE OF NITROGLYCERIN AS A THERAPEUTIC AGENT.*

By H. P. LOOMIS, M.D.,

NEW YORK.

It is difficult to explain why certain drugs have come into such general use unless it is a question of fashion as in other things, nor are we ever right in assuming that their popularity assures their value, much less their permanency. The study of the physiological action of drugs, first upon animals and then upon man, furnishes of course the only scientific and reliable method we have, of predicting future usefulness in the treatment of disease; still it is before the result of clinical experience alone that a drug must take or lose its place in the world's pharmacopeia.

Ever since the introduction of amyl nitrite to the profession by Lauder Brunton in 1867, the nitrites have occupied an established place in our materia medica. This is no doubt due to a great extent to the remarkable effect produced by the inhalation of amyl nitrite upon many patients in the anguish of angina pectoris and the relief obtained. Dr. Brunton, who discovered this drug and inferred its therapeutic effect from a study of its physiological action, certainly conferred a boon upon a hitherto almost helpless class of patients.

Of the three nitrites, amyl nitrite, nitrite of sodium, and nitroglycerin, the latter is to-day the most universally used, most probably because the cases which it is supposed to benefit are much more common than are cases of angina pectoris.

I have made inquiries lately of three of the largest dispensing pharmacists in this city, and they all tell me that prescriptions calling for nitroglycerin have greatly increased during the past two years, and that more of the drug is being used to-day than ever before. The wholesale houses also confirm this statement, so I think I may be warranted in saying that nitroglycerin is in quite extensive use to-day by the physicians in New York. It may be interesting to note that many of the largest dispensing druggists obtain their supply of nitroglycerin in a 10 per cent. alcoholic solution from the same source —a wholesale manufacturing house devoted exclusively to preparing homeopathic drugs. By inquiring I found that nitroglycerin is more generally prescribed here in New York in the form of tablets, although some still use the spiritus glonoini. Both of these preparations are considered pharmaceutically to be perfectly reliable and to keep well.

All these nitrites act in the same way and it is probable that this similarity of action depends upon the nitrous element in each of the preparations. The most characteristic action of these drugs is supposed to be their effect upon the vascular system, namely, their power to relax the whole arterial system and greatly reduce arterial pressure; they are supposed to produce this effect as the result of direct action upon the muscles within the arterial walls.

It has been observed under their use that the frequency of the heart's action is increased, but this has been explained by the sudden fall of blood pressure from dilatation of the vessels and not by any direct effect upon the heart itself. The intrinsic changes in the circulation increasing the supply of blood to the respiratory centers in the medulla stimulate them, and as a result the respirations are increased.

*Read at a meeting of the N. Y. Academy of Medicine, February 2, 1905.

Of the three nitrites, nitroglycerin is considered to be the most powerful, its alleviating effects more prolonged, and to be better suited for internal use, Nitrite of amyl is more rapid in effect, more transient, and better suited to external use by inhalation. Nitrite of sodium is considered by some to be more permanent in its effects but less stable than either of the other two. The symptoms which nitroglycerin causes in a healthy man in full doses are pulsation in the head, sometimes over the entire body, with giddiness and constriction or fullness of the head, generally amounting to a severe headache. If the person keeps quiet these symptoms are slight, but they are greatly increased by motion, and especially by stooping. The person does not feel sick, nor is there any mental confusion. After about a half-hour he generally begins to feel drowsy. From the beginning the heart action is rapid, the pulse being increased about 20 beats, and the arterial pressure lessened. The headache is the prominent symptom, and it often lasts until next day. It is a common symptom among the workmen in nitroglycerin works. These are the effects seen upon a healthy man who is susceptible to its influence. When the drug is given in diseased conditions where it is indicated none of these symptoms is developed, and it is remarkable what large doses such people take. I have often seen them take 1-10 grain every hour for a long time. The question that interests us as physicians is, does the drug in diseased conditions produce the one characteristic effect—of which practical advantage can be taken, namely, the dilatation of the arteries?

The statement that nitroglycerin causes dilatation of the arteries and reduces arterial pressure, has been handed down as a proven fact for a number of years in the various text books on materia medica and therapeutics. I will try to show you from a number of experiments I have made on dogs how difficult it is to prove this. One is impressed with the fact that the majority of writers have not tested this statement themselves, but have reiterated what the old writers have said, and taken for granted it is true. The result is that many members of the profession, especially the younger, have come to have implicit faith in this drug and use it in every case where the arteries are over-contracted, as seen in so many cases of general arterial sclerosis, Bright's disease, and failing heart. No doubt the fallaciousness of the time-honored custom of estimating the blood pressure by palpating the pulse, is in a large measure responsible for its estimated results in disease. How erroneous our former judgments were in this respect, the use of the sphygmomanometer by any one for a short time will be convincing. From my clinical observations I have questioned for a number of years whether nitroglycerin would do what was claimed for it, and it was with the endeavor to settle this point in my own mind that I have made some clinical tests this winter.

I have drawn my conclusions of its effects upon arteries by accurate and repeated readings of Riva-Rocci's sphymomanometer (using Cook's modification as adapted at the Johns Hopkins Hospital). The sphygmomanometer is the only practical method we possess of estimating the amount of arterial tension and changes in arterial pressure. For comparative readings in the same individual it is perfectly accurate. For the tests I selected cases which would generally be considered ideal ones for the use of nitroglycerin—cases in which arterial tension and high arterial pressure were the prominent factors and were the direct cause of most of the symptoms. In these cases nitroglycerin was given in large doses, over a long period of time

and frequently; the latter because it has been claimed by many pharmacologists that its action while pronounced, does not continue long, and to get permanent results the dose must be repeated often. In some cases to obviate the danger of incomplete absorption, the nitroglycerin was given hypodermically. The arterial pressure was taken by the sphygmomanometer before the nitroglycerin was given and during its use, in many cases hourly. The results were very different from what we would expect.

Let me ask your attention for a moment to the clinical results of the use of nitroglycerin in one or two cases. I need not go into the detail of its use in other cases, the results were practically the same.

Case I.—A man 46 years of age presented himself at Bellevue Hospital last October with the classical symptoms of the cirrhotic kidney, general arterial fibrosis, and a strong hypertrophied heart, free from murmurs and myocardial changes. He had only been sick as he claimed for a few days and had been working up to the day of admission. Upon being questioned, he acknowledged that for over a year he had had very severe headache and noticed that he was not as strong as he used to be. An acute swelling of the feet brought him to the hospital. Repeated examination of the urine always showed it to be of low specific gravity (below 1010) and to contain only a trace of albumin and a few casts. The amount of urine was large, being never less than 66 ounces per day. The arterial tension at the time of admission was very high, the sphygmomanometer registered 260 mm. of mercury pressure (145 mm. is, as you know, considered normal). The patient was put to bed and on an exclusive milk diet. His bowels were thoroughly acted on by calomel followed by a saline. The only medicine given was 20 grains of acetate of potassium every 4 hours. This plan of treatment was carried out for two weeks, and the arterial pressure was reduced so that the sphygmomanometer read 225 mm. pressure. This diminished tension was reached at the end of the first five days and showed no practical change during the next ten, so the case as far as the arterial tension went was at a standstill. Nitroglycerin was now commenced and given in doses of 1-50 grain in the form of the spiritus glonoini every hour during the day and every 3 hours at night. This was continued for 48 hours; 24 doses were given in 2 days. At the time of commencing the nitroglycerin the blood pressure was 225 mm.; at the end of 48 hours the sphygmomanometer registered 235 mm. As no effect was noted on the blood pressure the nitroglycerin was continued another 48 hours, and the patient received 16 doses each 24 hours. The blood pressure then registered 245 mm., or higher than it did when the nitroglycerin was commenced. Nitroglycerin was continued for 6 days longer, 1-50 grain given every hour during the day and three doses at night, and at the end of that time the instrument registered 230 mm., a reduction of only 15 points. To see if some effect on the blood pressure could not be obtained, nitroglycerin was now given hypodermically every 20 minutes for 18 doses, and the blood pressure was only reduced from 230 mm. to 223. These large doses of the drug produced no unpleasant effects, the pulse was not increased nor the headache perceptibly changed, nor was any effect on the arterial tension appreciable. Let me ask your attention for a moment to another case in which I used nitroglycerin.

Case II.—A painter, 38 years of age, entered Bellevue Hospital, complaining of dyspnea, some swelling of his feet, weakness, headache, and impairment of eyesight. On examination the diagnosis of chronic Bright's disease was made. The acute exacerbation from which he suffered was brought about by a cold, contracted a week previous. The heart was rapid and overacting, enlarged to the left, but no murmurs were detected. The pulse was incompressible and of high tension, the Riva-Rocci apparatus indicating 226 mm. of mercury pressure. He was put on an exclusive milk diet and calomel was given to move his bowels. No other medicine was given until at the end of the 48 hours, when nitroglycerin, 1-50 grain hypodermically, was commenced, and given every hour night and day. The blood pressure was taken every hour except at night. At the beginning, the pressure registered 226 mm., and at the end of 24 hours 243 mm. At the end of the second 24 hours, the nitroglycerin being continued hypodermically every hour, the blood pressure registered 235 mm. The net result after the continued use of nitroglycerin for 48 hours, showed no changes in the arteries or diminution in the blood pressure, but in fact a rise from 226 to 235. No change was observed in the headaches nor in the amount of urine secreted, which was averaging about 24 ounces each 24 hours. Nitroglycerin was now stopped and nitrite of sodium, gr. v by mouth, was given every hour, night and day, for 24 hours, at the end of which time the blood pressure had fallen from 235 mm. to 203 mm. The headache has improved and the urine increased by 6 ounces. After this the nitrite of sodium was continued in 5-grain doses every 4 hours, combined with 5 grains of chloral and diuretics. After the nitroglycerin was stopped the patient was put on diuretics and made a rapid recovery, and by the end of a week was free from symptoms and ready to leave the hospital.

It is needless for me to burden you with the details of other cases. The results obtained in these two cases are typical of those obtained in a number of similar cases in which I tested nitroglycerin. In none of them was any appreciable effect produced upon the blood pressure as tested by the sphygmomanometer, or upon the arterial tension as gauged by the character of the pulse. That there might be no question as to the efficiency of the nitroglycerin used, I did not confine myself to that furnished by the hospital, but obtained freshly made preparations from other reliable sources; with all, the results were the same. To see what the effect of nitroglycerin would be upon healthy arteries and upon the blood pressure of a normal individual, I took a man in perfect health, an Irishman, 40 years of age, employed about the hospital, and gave him 1-50 grain of nitroglycerin every hour, for eight doses. Only after receiving the last dose did he complain of any physiological effects, and that was a slight headache that persisted for two hours. When the nitroglycerin was commenced his blood pressure registered 142 mm. (normal) and after the last dose 150 mm. —a rise instead of a fall. His pulse remained the same.

I have tried nitroglycerin on a number of healthy individuals and have observed that people vary greatly in their susceptibility to its influences. A great many are not affected at all, even by large and repeated doses, especially people in the lower walks of life, and of phlegmatic temperament. Upon highstrung, nervous individuals, it is very apt to show its effects in congestive headaches. I have also noted a peculiar effect in the way the drug is taken. On some people a tablet of 1-100 grain by the stomach will produce no effect, but let that same individual dissolve a 1-100 grain tablet in the mouth

and the physiological effect of the drug will be notable.

To ascertain the effects of nitroglycerin upon the blood pressure in animals, I experimented, assisted by Dr. Robert Hatcher of the pharmacological laboratory of Cornell University, upon two anesthetized dogs. The float of a mercury manometer was connected by a cannula directly with the carotid artery so as to register the pulse rate and blood pressure on a revolving drum. Nitroglycerin was given hypodermically 1 mg. per kg. of weight and its effects noted. Larger doses were then given and effects noted, and finally the nitroglycerin was injected directly into the jugular vein. I might tabulate the following as the result of the experiments:

1. An ordinary dose of nitroglycerin, namely, that corresponding to 1-100 gr. in a man, did not affect the blood pressure at all.

2. To get a marked drop in blood pressure, an amount of nitroglycerin which would be excessive in a man must be given to the dog, one that would correspond to 1-3 to 1 grain to a man of 150 lbs. weight.

3. The heart action was weakened by every full dose given, as shown by the lessened excursion of the pointer on the drum.

4. Nitroglycerin injected into the jugular vein of a dog in amount equal to two grains to an adult man, caused the blood pressure to fall rapidly and markedly, and the heart at the same time was excessively weakened.

5. The fall in blood pressure from nitroglycerin was comparatively transient and entirely over in about five minutes, but the weakness of the heart continued.

6. An oncometer placed upon the kidney showed a prompt and marked diminution of that organ occurring simultaneously with the fall in blood pressure. This would seem to prove conclusively that it was not dilatation of the arteries that affected the readings.

I am aware that the conclusions which I would offer as the results of my clinical observations are different from generally accepted effects supposed to be obtained by the administration of nitroglycerin in arteriosclerosis, namely, a dilatation of the arteries, a lowering of the blood pressure, a widening of the blood paths, and a lessening of the work of the heart. At the same time I am aware from questioning a number of hospital clinicians, that there is a growing tendency to doubt the usefulness of this drug, and I have found from inquiries that its use in the metropolitan hospitals is very much less than it was.

I think we can all recall in our private practices cases that appeared to be markedly benefited by taking 1-100 grain nitroglycerin tablets, and when continued for a time the arterial tension appeared to be less and certainly some of the symptoms, such as headaches, was relieved. I think if we will analyze these cases we will find that it was only in the very earliest stages of high arterial tension that nitroglycerin produced these clinical results, and even here we must not lose sight of the fact that some of the beneficial effects seen during the use of nitroglycerin on private patients who know what they are taking may be mental. There is a great deal in the name, nitroglycerin. The point which I want to make is that when arteriofibrosis is thoroughly established one might as well try to dilate an iron tube by atmospheric pressure as one of these tense arteries by nitroglycerin. In many cases of angina pectoris I have seen permanent benefit from nitroglycerin. It is superior to amyl nitrite in affecting the underlying condition, for with the latter drug often the relief is only transient, but with the former it is permanent. Nitroglycerin is too slow to relieve the pain of a paroxysm; here we use amyl nitrite and it should be reserved for these occasions. Nitroglycerin being more continuous in its action may be given at stated intervals, say, every three hours. The regular administration greatly lessens the frequency of the attacks. Nitroglycerin has been used for a long time to relieve migrainous headache. My experience has been that sometimes it is very efficacious, but just as often it fails. I know of no way to decide in any given case except to try it; it certainly is more apt to be effective after forty than before. It should be given at least 1-100 grain every hour immediately the headache begins.

As a result of these clinical and laboratory observations I would offer the following conclusions:

1. The usual dose of nitroglycerin (1-100 grain) is too small to produce any effect in pathological conditions; 1-50 grain is a minimum dose.

2. It is a perfectly safe drug to use. Even in the large and repeated doses used I have never seen any ill effects.

3. High arterial pressure in man is not perceptibly affected by it, nor is dilatation of the blood-vessels apparent.

4. Its effects are very transient as shown by the experiments on the dogs, and the ordinary dose of 1-100 grain every 4 hours could not possibly have any effect on the arteries.

5. Nitroglycerin is said to increase the quantity of urine in chronic Bright's disease, but after keeping accurate records of the daily amount of urine passed, I was never able to satisfy myself that any increase seen was due to this drug.

6. I believe that in conditions due to arterial spasm so called, such as angina pectoris, migraine, and asthma, nitroglycerin may be of benefit, in full doses often repeated, but not in arterial sclerosis where the arteries themselves are more or less changed.

Before closing I would like to mention a drug, which in my experience has given most satisfactory results, in relaxing the arteries and diminishing blood pressure in arterial sclerosis. I refer to chloral hydrate, given in five-grain doses every four hours night and day. The effects are extraordinarily uniform. The sphygmomanometer will generally show a marked fall of pressure in twenty-four hours, and the distressing symptom of headache will generally be controlled. At the New York Hospital during my service and as well as that of my colleagues, Dr. Peabody and Dr. Lambert, nitroglycerin has been entirely discarded in arterial sclerosis and chloral hydrate has taken its place.

PSYCHOLOGICAL AIDS; OR THE PRACTICAL USE OF WELL-KNOWN LAWS OF THE MIND.

By EUGENE COLEMAN SAVIDGE, M.D.,

NEW YORK.

Life has been defined as "the sum total of forces that resist death." And death always wins in the end. Medical men are fighting a sure victor. However easy the struggle to-day, behind it, sooner or later, is the sure defeat. While the full complement of force is not always needed, it is nevertheless important to keep it instantly available against the outmeasuring foe.

I believe we can add to our resources by cataloguing these well-known laws of the mind. That we may find therein an intangible quality which makes one man's calomel or digitalis better than an-

other man's. And that the greatest materialist of the laboratory himself, who would most warmly resent such a statement, will be the first to give us the material scale by which can be expressed in volumetric terms this distinct difference.

I have elsewhere written, and by no means fancifully, about putting "a meter on the power for healing in the human mind," by indicating in mechanical terms, respectively, the measure of the destruction, and of the saving of the red-blood corpuscles by anxiety and by relief from anxiety. This is one of the nearest scientific possibilities. For though they are the practical basis of life itself, it is common knowledge how quickly these red-blood corpuscles are destroyed by anxiety or fear. Thus the very citadel of a man's vitality is exposed to an attack from an intangible thought. Conversely, can there be physical addition to this citadel—by stopping the loss. When comes to the bedside the best available exponent of wisdom, honesty and skill—which the medical man should always symbolize to his patient—a certain anxiety is quelled.* A certain cause of red blood corpuscle destruction is removed. There is, therefore, physical, measurable addition at the very foundation of life. The optimistic therapeutist will therefore get a better blood count than the resigned and somber pathologist.

It is in this sense that an eye-glance or an unweighable thought does weighable things, and makes one man's digitalis better than another man's. It explains why the professional assertiveness of the high-class man has a value. We see this every day, when the mere assent of the famous consultant adds efficiency to measures already in effect. Medical men will freely confess that as their position grows their old formulæ do better work; that the prescription, once written for a dollar, rises correspondingly in effect when its cost is ten dollars. The leading medical man of a town, like the leading hatter, might dispense the identical quality obtainable elsewhere, and still give more—namely, the consciousness, lasting and soothing, that the best has been had. This law of the mind is as strong as the necessity underlying the insistence on reverence for matters sacred, the respect for the flag, for the court, for decorum in the presence of good women.

Apparent, then, is the error that tariff rules apply to professional service. I try to rebuke this misconception in the shrewd ones of the world as I meet them yearly going abroad for cheap professional work. A wealthy man, within my knowledge, paid for a lithopaxy in a small German town about the price of a New York consultation, and then felicitated himself upon having circumvented the profession. As a result, his commercial estimate of professional things—a definite tariff for a visible service applied for—kept him out of observation until too late for help, and I believe it cost him ten years of useful life. The same rule applies to those who in disguise seek stolen opinions through the dispensaries, or who pose under their station in the consulting room. The bearing of correlative matters is left out of account; they lose instead of gain.

Therefore the honor accorded the physician, the respect demanded by him, make the digitalis of honor stronger than that of indifference.

The most inviting field for our subject, however, is in the field of chronic troubles, and in the almost virgin domain of Synthetical Medicine, to which I shall recur later. Chronic troubles are the harvest of the charlatan. Here thrive all the "cures"—movement, electricity, herb, water, Kneipp, Dowie, relic, faith, osteopath, and Mother Eddy. And the medical man who lets his prejudice blind him to the fragments of misapplied truths held by these cults is simply adding to the spread of what he most opposes. For each brings into play, more by ignorance than by design, these subtle laws of the mind which medical men are the most apt to neglect or distrust. Medicine was formerly a monopoly of the occult, the esoteric, the priest and "medicine man"; and modern medicine grew out of the reaction from the ancient deceptions and abuses. This very fact impels the medical man all the more to distrust all that cannot be touched, shown, or measured. Realizing the narrow line between "fake" and the proper use of certain powers within our grasp, can medical men get any practical help from the realm of psychology? Most certainly.

Vitality is what we want in fighting death. Is it an over-claim to say that the greatest vitality is found where the alertness of the nervous system is the greatest? Witness the Hebrew race. Note that in the shipwrecks, disasters, and Arctic expeditions of history it has been the men of brain—sustained by energy, hope, and interest—who have outlived those of less alert nervous structure. If this be so, what follows? Enhancing the alertness of the nervous system increases vitality—which is our aim.

Compare the vividness and freshness of impressions in youth with the duller states of consciousness in age. Hear a child observing the surface matters of a new scene. Compare the relatively young impressions of an adult in new surroundings with those of the same adult in routine environment. Take a man's morning walk to his office, and see how quickly he notices a new sign put out over night. He is old to everything else on that walk, but young to the new sign. He has more "vitality" with reference to the new sign than to any like object in the routine. Monotony, therefore, is the old age of youth. Change, "the joy of the dissimilar," is youth in old age. Indeed, change is the very basis of consciousness itself.

Herbert Spencer says: "It is admitted on all hands that without change consciousness is impossible; consciousness ceases when change in consciousness ceases. . . . Change, as known by us, is the unlikeness of a present state of consciousness to a past state."

In change, therefore, we have an almost weighable vitality to add to our patients. The mental processes of the adult—introspection, retrospection, and logical deduction—use different parts of the mind from those used by the child, who is noting the difference on the surface of things. Whatever attracts the peripheral attention, therefore, rests the adult processes and employs the child processes, drawing the blood from the great nerve centers as surely as though it were pumped. We can thus cup the brain, and empty the great throbbing bags of blood in the central vessels, by putting one under the influence of new surroundings, new architecture, new customs, with their surface-attention demands. Even the most unwilling or downright of individuals is susceptible under this process. Are we not thereby practically administering a decoction of youth when we cause the introspective adult to turn his eyes outward upon the surface of things, as does the child?

Endless examples illustrate this truth. Note the necessity of the highly-evolved race or individual for stimulation in the peripheral areas. As the lower order can never understand the next higher order, this necessity is not understood by the duller of nerve structure. Scan the faces in the stream of travel, at the opera, at the play. See how the highly

* See comparative pulse tracings in plates reported by Dr. C. E. Quimby, in the *Journal of the American Medical Association*, March 15, 1902; and also remarks upon the effect of "the varied forms of life's mental annoyances" in organic heart troubles, as illustrated by pulse tracings.

evolved cluster in the cities, and consider the constant drag cityward of the bright minds from the provinces. Compare the relative aging of individuals, respectively, under monotony and under peripheral changes readily at hand. Even race horses are said to be improved by hanging toys over their stalls to train more highly the nervous system, and so enhance endurance.

If change be the basis of consciousness, and if more "consciousness" increases vitality, what of monotony? Monotony, after the certain point necessary to fix all training, lessens vitality. That continuous impressions will finally wear out susceptibility is one of the best known laws of the nervous system. Stimulate a frog's leg with your battery and you get a reaction; again, and once more a reaction—until finally there is no response. Rest, and try again, and once more you have susceptibility. There has been a temporary death to perceptions. Thus even so stable an element, apparently, as primary color takes on its complementary aspect by too much gazing.

But even before the constantly-used functions tire out the unused, auxiliary ones fail. A. M. Bloch (*Revue Scientifique,* June 6, 1903) has shown that it is not the used muscles that tire earliest under incessant labor; but, paradoxical as it may seem, *the muscular groups that remain still are first tired, while those that contract and relax constantly, even in incessant toil, accomplish their task with much greater ease.* The significance of this is great. The gold-beater may not get tired first in his biceps, but in the back and loins. The young soldier after a march is tired in back and neck, not in his legs. The oarsman suffers first in calves and insteps; and so on, through the list. The dominant fatigue is in the *accessory* groups. The analogy in the nervous system holds true. One grows "stale" to the environment; the routine faculties are the last to show fatigue; the "unused props of the soul" are the first to tire; the apathy begins in the auxiliary faculties.

Hence certain great laws of the nervous system stand out. In order to make of them entities with handles for quick use, they might be put this way: (*a*) The law of novelty; (*b*) the law of monotony; (*c*) the law of peripheral change; (*d*) the law of central stability.

The Law of Novelty.—There is more vitality in the attraction and repulsion of the new, because there is greater consciousness of difference. No human being is exempt from this law. It frees nerve cells from their tension. It is a draught of youth. Jove, laughing at lovers' vows, was thinking of this law and its opposite. This explains the success of the interregnum plan of treatment for chronic troubles, and why the new doctor is always great—for a time.

One goes down one's own staircase automatically, with one's spinal cord. There is neither memory nor reason in this automatic reflex action. A strange staircase, requiring perception, is therefore a tonic because an exercise of a higher center than the spinal cord—bringing into action the part of the being where lies the source of vitality.

The Law of Monotony.—No one is exempt from it. It is of the greatest necessity. It fixes all training. "It is what the soldier does after his first year." It passes rational actions into automatic or instinctive actions. One grows into its mould and form, in a manner not far removed from vegetable life.

Monotony has a therapeutic value as well as novelty, for there are times when the superactivity of a nervous system requires the quieting hand of sameness. But its over-effect is rut, vegetation, age, and then death; and this is best met by frankly fronting the fact and meeting is requirements when proper.

The Law of Peripheral Change.—Surface impressions release tension on the deep centers. They should be changed as often as reasonable for the designed purpose of getting the vitality hidden therein. Freshness, vividness, youth, effective longevity lie here. A man is old the moment he ceases to do new things, to diminish his mobility. Rut, therefore, lessens mobility; consequently intelligence, consequently vitality.

Men willingly exercise a biceps, or a calf muscle, to keep it in condition; but forget there is a fading mental capacity—the susceptibility to all those mental impressions that are born under certain stimulus. Is it not distinctly allowing a known narrowing of the area of consciousness, hence a dwindling of that entity on which vitality depends?

The Law of Central Stability.—This law lies at the basis of conviction, honor, loyalty, character. It is the theologian's law. It is the holding on, in the storm of passion or the paralysis of discouragement, to the purpose laid in reason's calm.

These central basal elements are all the more firmly known and held by separating them sharply from the unimportant peripheral matters. Provincial fidelity to the locality—almost to the building lot—does not mean a firmer devotion to one's basal ideals; indeed, it is often exactly the contrary, as is witnessed by the large number of "shut-ins"—farmers' wives, and the like—who go insane, *i. e.,* lose their central stability. The dynamics under this law should always be available to the medical man.

Before coming to practical recommendations, the following illustrations bearing upon the subject are cited:

The cough that nothing will cure in the city gets well when the patient goes to the country, and vice versa.

The "dyspepsia" of the clerk and letter-carrier are the same; but a short change of each to the work of the other would cure both.

Outdoor life invigorates those shut in, but workers in the open air have their own vicissitudes. It is the change which works most of the miracle.

Often one can eat better out of the usual time and place, and after sleepless nights it seems easy to sleep anywhere but in bed and at night.

The tune, the flower, that at first was delight, in time becomes odious. There is unsuspected beauty in "the old songs" after long enough interval.

Thus frequent repetition destroys the significance of a poem or prayer; but there is a joy of the hackneyed through the medium of a foreign tongue. Even cant, translated, acquires its pristine value.

Note the difficulty of conversation at family gatherings. One strange face at the hearth immediately adds a wider range of interests.

The associational fibers of the brain are stimulated by a return to the scenes of one's youth. Memories thought dead are made alive. There is more mind at such a moment.

The effect of mind on nutrition is seen by the immediate failure of nutrition when a paralysis cuts a muscle off from its higher connection. The blood supply is not cut off; it is a nerve matter. Conversely, trainers make you put your mind on the muscle you want to build up. A mind-directed contraction builds more than an automatic spinal cord contraction.

The quivering restlessness—sometimes healthy, sometimes diseased—of the most successful of the world, shifting from clime to clime, illustrates the law that the degree of mobility is related to the degree of nervous development.

The sphynx-like problem, inscrutable at night, smiles its Eureka in the morning. One is then holding, as by brevet, a higher mental rank, seeing phases as non-existent the night before as the scent followed by the bloodhound is to man.

In extreme fatigue there is desired no poem, nor music, nor prayer, nor plan, nor line of beauty, nor initiative concept—illustrating that in an exhaustion of vitality the latest and highest faculties are gone. This is a demotion of nerve rank; one has then less of mind; one is again a private in the psychological ranks. One still has one's automatic reflexes, as has the lout; but not much more.

And, finally, who has not seen that condition of tension in tired man or woman, in whom each additional degree of nerve exhaustion but arouses a greater super-conscientiousness, pushing morbidly to more effort, to greater tension, at more rapid pace, making it impossible for any but an extraneous will to say: "Stop, look, listen." And what are the reasons for not arresting such short-circuiting of the nervous system? A poorly applied economy, a false sense of duty, and scant idea of comparative values.

I have seen a wife deliberately get pneumonia because her husband had it, morbidly fancying she was devoted in so doing, when she was only endangering his convalescence. I have seen a mother with nervous system tapped constantly by the child over whom she yearned, resent as infidelity the advice to help her child by getting herself into condition. I have seen husband, wife, business partner let self-effacement, self-denial, deference for others; constant, futile activity beyond the fatigue line, simply condemn the partner for whom the efforts were made to union with an automatic reflex, instead of a self-determinating being of proper mental rank. And yet it is as dangerous as heresy to say the reasonable thing in such cases; to preach that unselfishness which gratifies a morbidness is the most costly selfishness; and that guarding one's effectiveness for the supreme use when needed is following the example of the Founder of Christianity, who conserved life for thirty-three years for the one ultimate self-sacrifice. Despite similar warnings valuable, career-producing lives have been lost because these minor, almost morbid, unselfishnesses have been indulged at the expense of the greater comparative value.

Great vital force in this neglected life-waste is therefore available to medical men for practical use. But one must see the opportunity as well as know the law. The field of chronic troubles is thoroughly known. But the greatest opportunity lies in a field almost virgin to the profession. This field of *Synthetical Medicine*, tentatively so called by the writer, is therefore interpolated here.

Synthetical medicine, upon which the writer has done pioneer writing for the last decade, is as distinctive in domain as Preventive Medicine. Preventive medicine includes all the comprehensive measures of hygiene, vaccination, antisepsis, quarantine, and military medical supervision—now focussed to as fine a point as shooting a soldier on campaign who drinks unapproved water—which have conserved human life everywhere to figures beyond computation. A return to conditions of a century ago would bring an appalling rise in mortality. Yet the work is nearly all recent.

Synthetical medicine, on the other hand, deals with the individual instead of the community. It is restricted to those who are self-guiding and provident, who study to get the best from their brain-pan full of protoplasm; it is hopeless with the rabble. It assumes to recognize and postpone that eventual trouble, be it in heart, liver, kidney or blood-vessel, which a grouping and study of present conditions will often show years before it takes its classified text-book form. That this can be done by capable medical men is my most earnest conviction. If so, the immense importance of the subject to community, medical economics and life insurance is at once apparent. Study the necrology of the last decade, even in this one country, and consider what an average of five years more to each of these elect of civilization would have meant for the family, community, and race. A man like Pasteur is more valuable to France than many regiments of soldiers.

Synthetical medicine, therefore, saving the waste of the most valuable kind of life—the lives of those who are contributing to their age—will yield the highest medical rewards of the future, and restore to medical men the revenue robbed from them by their own success in preventive medicine.

It is in the synthetical department of medicine that the laws of the mind are the most important. A trainer is deemed necessary for the fistic encounter or the football field. Every man who is his own lawyer has a fool for a client. Medical men are proverbially the worst patients. Yet every human being feels qualified to direct his intricate mental and physical mechanism through the strains of life. Given a youth his endowment of health; what will he do with it? Is it not like trusting a fortune in cash to the jejune for investment?

Therefore, as the athlete gets "stale" to his exercise, so does the individual to every relation in life. The tired man has submerged his higher faculties; he has reduced himself to his primitive automatic reflexes; he is to that degree an incompetent. How few keep proper susceptibilities toward their own family, home, or business? How much easier to criticise capably another man's environment than our own. One is a smaller mental man toward the familiar than facing the new. It is here the greatest life-wastes occur; here is the greatest opportunity for "the extraneous will"; for the best results in chronic conditions, and the training for effective longevity.

"Travel," as a remedy, has been crystallized almost to the rubber-stamp degree. Even the funny papers caricature the doctor as advising his patient to give up all his business and go somewhere else. As potent psychology as travel is, it is often useless to prescribe it; as, for example, to one whose grief is financial. Yet the law of "peripheral change" can be applied at home.

The big trees, fruits, animals and men of California show what differences favoring environment will make. So also the physical supremacy of the present generation of Americans over the last. The man with "brains" and the man without them are like creatures from different planets; yet far enough back in the ancestral line an environmental difference started them apart. Medical men, therefore—the physical directors of humanity—realizing this power, and seeing where to apply it, can make, artificially, so to speak, the genial climate right where a man's duty holds him.

Once the methods are understood, the conditions become self-suggestive. One instinctively attacks the larger affairs of life when holding one's highest mental rank. But, leaving aside the new subject of synthetical medicine, and all that is implied in training for effective longevity, what practical help can our subject give the physician? Assume a case of supreme nerve prostraton from financial or domestic grief in which drugs fail. The following sample expedients are based upon these well-known laws of the mind:

First: Separate the patient from the scene of his

troubles as far as possible—even if necessary to order new temporary sleeping and business quarters.

Second: Restrict all discussion of troubles to the morning hours. Absolutely forbid reference thereto at night.

Third: Occupy him with his periphery, by ordering Turkish bath, massage, shave, hair-cut, manicure, and have him arrayed in his best garb, etc.

Fourth: Interpose some one, disinterested in his sore thought, between him and his conjugal or business partner.

Fifth: Seek gentle exercise for his atrophied auxiliary faculties. These faculties, not directly connected with life-serving functions, seem hopelessly fatigued and rudimentary. All the play impulses, such as sports and games, are of this class. And play seems the most impossible, inhuman suggestion to the patient, feeling, as he does, his greatest withering in just these faculties; he still has his routine reflexes. Send such a patient, whose reason may be tottering, with an equable friend to insist on peripheral attention, and the gentle exercise of his neglected faculties. Prescribe some childish contest, like the following: That the one-syllable business signs will exceed the two-syllable signs on the route about town, or the number of gilt exceed the silver. Or, in the country, make a contest on the relation of budding or autumnal change to the species of plant or tree, or with relation to the points of the compass. Or, again, I have prescribed the problem of Houdin—to compete in naming the contents of a window in passing, then returning to verify it. The more trivial the contest the more successful, sometimes, in drawing blood from the deep centers to the surface.

Sixth: Apply the power in the law of central stability. Bring to the front the patient's basal elements of character. Suppose a strong medical man had put this "central law" behind Napoleon, when early in his disasters he sat for days drawing meaningless circles on paper; or, when ill from self-poisoning at Fontainebleau, he allowed his higher faculties to escape him. What might not have done the basal elements of that character? This was a physician's opportunity to change history. These are Napoleon's later words: "It is only by daring that one does anything worth the doing. It is only from the feeling of good fortune that one ever dares. Misfortune crushes and blasts the mind, and thenceforth one does nothing well." (Compare Virgil "They are able because they seem to themselves to be able.")

The great law of central purpose and conviction under a bruised nervous system may sometimes equal in power the "feeling of good fortune"; and who can apply this law but the medical man?

Endless similar plans will yield the lost vitality in these nerve wastes; and vitality is what we want. "Do you exercise?" must often be amended to "Do you exercise your periphery?"—at the risk of startling some who never discuss delicate matters.

And this impels me to caution against the use of psychological jargon with those whose thoughts run in theological crystals. For some good souls think a steadfast faith includes a steadfast climate and periphery, and that it is disloyal and wicked to confess fatigue to prayer, husband, child, or home. And, while psychologists are debating the difference between impressions and sensations, vivid and faint, an immoral meaning may be read into the algebraic formula. It may be thought that you have recommended a frequent change of religion and conjugal partners.

There is, nevertheless, much life at the time of its greatest value in these powers when properly applied.

No. 66 West Fiftieth Street.

REPORT OF A CASE OF VAGINAL CESAREAN SECTION WITH RECOVERY.*

By SIMON STRAUSS, M.D.,

Lecturer on Gynecology in the New York Polyclinic.

Owing to the improved technique and rigid asepsis, cesarean section has of late been performed with increasing frequency and the indications have broadened considerably. Still there are certain objections to the abdominal cesarean section—the uterine scar may open in subsequent labors, there may be omental and intestinal adhesions, or hernia may result. Then of course there is more danger of sepsis, and in some cases of uncontrollable hemorrhage the uterus must be sacrificed to save the patient's life. Aside from these considerations, the patients and their relatives object to the operation, especially in this country, if done in the classical way.

Vaginal cesarean section requires that the bony pelvis be not too greatly contracted; and one should not attempt to do it with the conjugata vera below 8 cm. The technique is as follows: The patient is anesthetized and disinfected as for vaginal hysterectomy, the cervix is grasped with two vulsellum forceps and steadied, and a longitudinal incision is made in the anterior vaginal wall from 2 to 3 cm. below the meatus urinarius and extended as far as the external os. The bladder is then peeled off from the cervix and lower uterine segment, and an incision is made in the median line from the external os up to the peritoneal reflection, but the peritoneal cavity is not opened. The two vulsellum forceps have meanwhile been removed, and two stout sutures are introduced to steady the uterus, one on each side of the anterior incision. An incision is also made in the posterior vaginal wall about 3 cm. from the external os, and Douglas' cul-de-sac is peeled from the posterior wall of the lower uterine segment without opening the peritoneal cavity. The cervix is then incised posteriorly, from the external os, usually about 4 cm. in length. The membranes will then be seen to protrude, a foot is grasped, version is performed, and the child is extracted. One may also apply forceps and deliver in that manner, but version is preferred because the extraction is more easily accomplished. After delivery the cord is cut short and a large pad is introduced to keep the field clear for repairing the uterine wall. The placenta is expressed or manually removed. This latter method of procedure is recommended if there is much bleeding. The incisions in the uterus should be closed by interrupted sutures, and the vaginal wall closed by continuous sutures.

Mrs. D. aged 36, last menstruation 7½ months ago. She was subjected to operation in one of the large hospitals in this city some time ago, which resulted in cicatricial stenosis of the cervix. The patient had been in labor two days, with a slight flow of blood, and although there was intense pain there was no progress. The examination revealed the uterus four fingers above the umbilicus; the head was engaged in the pelvic brim, the small parts could be felt to the right above, but no fetal heart sounds could be heard. Internal examination revealed a broad, smooth surface with no semblance of cervix. All landmarks were destroyed such as pitting and depressions, which we generally feel when examining for the os.

The patient's temperature was 104°, pulse 130, and as she was evidently suffering from septic absorption

*Read at a meeting of the East Side Physicians' Association, New York City, October 18, 1904.

and in a serious condition it was decided to empty the uterus at once. Vaginal cesarean section was selected, as the abdominal operation would expose the peritoneum to infection, and by the vaginal route drainage could be more easily carried out.

The patient was anesthetized and disinfected. As all anatomical relations were destroyed, and there was great danger of injuring the bladder, a small tenaculum was introduced and the dissection was very carefully made; the peritoneum was reflected off a larger area than usual on account of the amputation of the cervix. The peritoneum was stripped off the bladder anteriorly. The uterus and Douglas' pouch were separated posteriorly in like manner. The uterus was incised anteriorly and posteriorly in the median line from the os externum to the peritoneal reflection, then the membranes were ruptured, and the child, which was dead, was delivered with the forceps. The placenta was expressed, and the uterus irrigated with salt solution, then packed with a 5 per cent. iodoform gauze, which was changed from time to time to prevent a recurrence of the stenosis. The patient's temperature dropped to 103° and the pulse to 116 in four hours, and they continued to drop so that after three days she had normal temperature and pulse. Convalescence was rapid and patient was out of bed in two weeks.

The indications for vaginal cesarean section are:

(1) Abnormalities of the cervix uteri as carcinoma, myoma, rigidity, and stenosis.

(2) Conditions in which the mother is in extremis.

(3) Conditions in which the mother has disease serious to life, as lung, heart, or kidney affections.

(4) Accidental hemorrhage with closed cervix.

The third indication is operative only when the cervix is closed and not dilatable, and we do not wish the patient to suffer from a long labor when there are severe heart or kidney lesions.

Vaginal cesarean section has a wide scope in cases of eclampsia, when the patient is water-logged, when she suffers from persistent headache, nausea, vomiting, rapid heart action, and amaurosis, and when there is no doubt that the uterus can be emptied in from 10 to 20 minutes, thereby saving great strain on organs already diseased and crippled. In cases of heart lesions, we can spare the patient many hours' suffering by performing vaginal cesarean section.

In cases of placenta prævia with rigidity, the supravaginal portion of the cervix not being dilatable, the operation should be done, as many a life has been sacrificed by temporizing with tampons and version. Time and experience will undoubtedly teach us many more indications for the performance of this operation, and I hope by bringing this method of procedure before your notice to induce its adoption for the saving of live and shortening the suffering of many cases that come under your care.

Sudden and Unexpected Death in Children, from a Surgical Point of View.—A. H. Tubby discusses this subject from the standpoint of "unexpectedly sudden death," first speaking of circulatory conditions. Hemophilia neonatorum is met with in the earliest days of life. Umbilical hemorrhage may be due to syphilis, pyemia, or lesions of the bile-ducts and liver. Some infants succumb shortly after birth to persistent hemorrhage from the umbilicus and intestinal canal. True hemophilia, so often noted in children, often gives rise to fatal consequences. Even a slight blow on the head has been the cause of a hemorrhage on the surface of the brain, or into the substance of the medulla, which is necessarily fatal. Death may be due to an ulcer in the stomach or duodenum, or to tuberculous ulcers in the jejunum. A possible cause of hemorrhage from the genital organs in newly-born children is the presence of a calculus. In older children a profuse flow of blood is sometimes due to sloughing of the pharynx and tonsils, a complication of scarlet fever of a very severe type. Noma may end in the same way. Fatal hemorrhage in connection with and after operation is preventable, and if it occurs must cause the surgeon keen anguish. Thrombosis and embolism are responsible for some tragic deaths. Especially is this true in relation to the injection of nævi with perchloride of iron and other substances, or during electrolysis. Many cases which are put down to shock should be more rightly ascribed to hemorrhage. But under shock should be considered cold, exposure, undue delay in operating, emptying cavities filled with fluid too rapidly, and washing out cavities. The effects of cold and exposure are especially seen in operations for intussusception, intestinal obstruction, and laminectomy. In emptying too rapidly the pleural cavity filled with fluid or pus, the shock is often profound. The writer believes that it is better to abstain from washing out the pleural cavity. Under toxic conditions, he considers chemical poisons and irritants, and toxic poisons. Of the former, carbolic acid and iodoform are in the most common use. In certain cases of appendicitis, sudden death sometimes occurs which is difficult to explain. In some of these cases it seems that a particularly active poison, with a cumulative effect, develops, and kills the patient. When the writer suspects such a condition, he freely plies the patient with strychnine, digitalis, and alcohol. Uremic poisoning is the cause of unexpected death after operations quite safe in themselves. Under "infective conditions" are grouped: tubercle, tetanus, acute edema of the tissues of the neck, acute malignant edema, and pyemia. There are records of cases in which operation has been done for the removal of a tuberculous lesion, and which was followed within two or three days by acute tuberculosis or tuberculous meningitis. The writer believes that this untoward event is most likely to occur in operations on bone and the scraping of tuberculous glands. Tetanus of newly-born children, due to lack of cleanliness in dressing the cord, is now almost a dream of the past. Pyemia in children is often rapidly and unusually fatal. Various mechanical conditions may be the cause of sudden death. The immediate results of the entrance of foreign bodies into the air-passages depend upon the size and nature of the foreign body. Papillomata of the larynx may attain such a size as to cause sudden asphyxia. Sometimes serious difficulty occurs in inducing children to do without the tracheotomy tube. In certain cases the presence of a large thyroid and persistent thymus lead to fatal results; so does the displacement of a cervical vertebra. The escape of cerebrospinal fluid during certain operations is sometimes followed by death. The writer concludes by suggesting certain rare and unusual causes of sudden death. One of these is the sucking of air into veins in operation upon the neck for the removal of tuberculous glands. Reference is also made to the dangers of acute peritonitis arising from an inflammation of a retained testis in the abdomen, the presence of salpingitis, associated with gonorrhea, in young children, and the sudden inflammation, suppuration, and bursting of a dermoid cyst.—*The British Journal of Children's Diseases.*

The Bacteriology of the Egyptian Deserts.—Engel made a series of determinations on various bacteriological questions in the neighborhood of Heluan. It was found that tubercle bacilli in sputum were killed on six hours' exposure to the sunlight, typhoid bacilli in one and a half hours, and staphylococci in two and a half hours. The average number of germs in 100 liters of air was only 28, a proportion comparable only to that of the polar regions and on the high seas. None of the germs were pathogenic to animals, and those cultivated from the soil were also harmless. The author considers the general meteorological and other conditions of the Egyptian deserts especially suitable for rheumatics, nephritics and gouty and tuberculous patients.—*Zeitschrift für klinische Medizin.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, March 18, 1905.

THE TOXIC EFFECTS OF FORMALDEHYD.

ALTHOUGH formaldehyd is not largely used medicinally, being employed principally as a disinfectant and preservative, it is nevertheless important to appreciate that whether inhaled, ingested by the stomach, or injected beneath the skin or into the blood vessels, the agent is capable of exerting distinctly injurious effects and causing irritative and even inflammatory and degenerative changes in various tissues of the body. This knowledge is particularly significant as supporting the position taken by those who deprecate the use for purposes of food-preservation of agents of the class to which formaldehyd belongs. With the view of reaching a definitive opinion in the matter, Dr. Martin H. Fischer (*Journal of Experimental Medicine*, February, 1905) has made a series of experimental observations, as a result of which he found that the inhalation of formaldehyd vapor, even in small quantities, is followed by the development of bronchitis and pneumonia, the latter being due to the inhalation, and not to secondary infection. Formalin—40 per cent. formaldehyd—belongs to that rare group of poisons that, when swallowed, are capable of causing sudden death. The introduction of formalin into the stomach is followed by the development of gastritis varying greatly in character. The duodenum and the upper portion of the jejunum may also be involved in the inflammatory process. Intraperitoneal injections of formalin cause peritonitis of fibrinohemorrhagic character. A definite reaction takes place when a dilution as high as 1 to 1,000 is employed.

Formalin exerts a destructive action upon all of the viscera contained in the peritoneal cavity—pancreas, liver, peritoneal fat, oviducts, etc.—with which it comes in contact, and it excites inflammation of these viscera. In guinea-pigs the lethal dose of formalin injected into the peritoneum is approximately 2 c.c. of a 1 to 1,000 solution for every gram of body weight. Injection of formalin into the lungs is followed by pneumonia and bronchitis. The inflammation that develops in the sequence of subcutaneous injection of formalin is characterized by intense exudation. Injection of formalin into the muscles causes myositis; into the anterior chamber of the eye, the accumulation of an exudate containing leucocytes and fibrin. Instillation of formalin into the conjunctival sac is followed by iritis, the intensity of which may be sufficient to cause destruction of the eye.

However introduced into the body, formalin is absorbed, and is then capable of inducing lesions in the parenchymatous organs. The changes in the liver following the absorption of formalin consist in a mild or severe degree of cloudy swelling, accompanied by vacuolation of the protoplasm, alterations in the nuclei, leucocytic infiltration, and, possibly, focal necrosis. Similar changes follow the inhalation of formaldehyd. Injection of formalin or inhalation of the vapors of formaldehyd causes cloudy swelling of the parenchyma of the kidney, possibly with focal necrosis. Pneumonia and bronchitis develop in all animals after injection of formalin.

The leucocytic infiltration following the introduction of formalin into an organ has the following general characteristics: Eosinophiles appear first, next other polynuclear leucocytes, finally large and small leucocytes. Similar phenomena occur in the trachea, bronchi, and lungs of animals subjected to inhalations of formaldehyd. Formalin exercises, directly or indirectly, a chemotactic influence upon the leucocytes. The tissues that are not infiltrated with leucocytes following injection of formalin are those that have been so injured by the chemical that no inflammatory reaction can take place. Animals subjected to chronic poisoning as a result of intraperitoneal injection develop fibrinous peritonitis, in conjunction with marked eosinophilia. The changes in the kidneys and the liver consist of cloudy swelling, fatty degeneration, focal necrosis, and leucocytic infiltration.

RECENT INVESTIGATIONS REGARDING TUBERCULOSIS.

THE first annual report of the Henry Phipps Institute, which has been recently issued, gives some interesting and valuable facts concerning tuberculosis.

Nearly one-half of all the patients registered at the Phipps Institute Hospital were foreign born. The foreign-born males exceeded the foreign-born females by about 19 per cent. More than one-half of the patients were between twenty and forty years of age. As to their social condition, two facts stand out conspicuously, one the number of married people, and the other the number of widowed. Forty per cent. of those who applied for assistance were married, and nearly nine per cent. were widowed.

Respecting the occupations of applicants, some very interesting points present themselves. The occupation from which the highest number came for treatment to the Phipps Institute during the year covered by the report was housework. The total number of women applicants was 851, and the number of houseworkers was 360. The other female occupations most numerously represented were, in respective order, factory hands, 47; weavers, 32; seamstresses, 33; laundry workers, 14; shop employees, 12, and nurses, 7. The male occupation at the head of the list is that of laborer, with 101. Tailors numbered 59; clerks, 43; cigarmakers, 30; salesmen, 13; printers, 14, and shoemakers, 12.

Another group is that in which alcohol plays a part. To this list belongs the occupation of driver, with 42; that of waiter, with 21; bartender, with 14; plumber, with 10, and cook, with 10. According to the figures in the report, however, the percentage of alcoholics among consumptives and among the relatives of consumptives does not seem to differ

very much from that of non-consumptives and relatives of non-consumptives. Another group is that in which occupation exposes to inhalation of irritating substances given off in manufacturing processes. To this group belong the occupation of mill-hand, with 64; machinist, with 35; weaver, with 32; ironworker, with 21; upholsterer, with 9.

With regard to those diseases generally termed predisposing to consumption, figures would seem to indicate that pleurisy most frequently precedes tuberculosis, pneumonia next, and typhoid fever last. So far as could be determined, exposure to contagion is, perhaps, the most prominent factor in the spread of tuberculosis. That is to say, the home plays an important part in the origin and dissemination of consumption.

The efforts made to determine the part of the lungs in which the disease began met with the following results: The side which had the most extensive lesion was recorded as the side on which the disease began. Although the records on this point cannot be regarded as wholly reliable, yet they strongly support the universally accepted view that the right lung is most frequently the first affected. A large percentage of the patients gave a history of hemoptysis, explained by the fact that the patients were drawn from the working classes, and consequently were liable to overexertion.

Regarding the duration of the disease, 1,460 cases were investigated, of which number 656 had suffered for less than two years, 485 for from two to five years, 171 for from five to ten years, and 148 for over ten years.

The results of treatment were as follows: Number of cases improved, 537; number of cases unimproved, 583; number of cases results not recorded, 884; number of cases terminated in death, 153.

One of the chief objects of the Institute is the prevention of tuberculosis, to which end all the dispensary patients are taught and drilled in preventive measures, and at regular intervals a patient is visited in his home by a pupil nurse and is given instruction and assistance as he may need for prevention of the spread of the disease. The removal of patients to the hospital from overcrowded, poverty-stricken homes, tends to prevent the spread of the disease, for such individuals are, under the conditions, active centers of infection.

Scientific research is one of the purposes of the Institute, and all means pointing to the study of tuberculosis are being adopted, and will, in the course of time, be carried out. The educational work of the Institute is also a prominent feature, and at the commencement of its first year an international lecture course was arranged. These lectures are published as a part of the first report. The lecturers were Drs. E. L. Trudeau of Saranac; Wm. Osler of Baltimore; G. Simms Woodhead of Cambridge, England; Hermann M. Biggs of New York; and Edoardo Maragliano of Italy, the latter represented by proxy.

The opening of the Phipps Institute was an event of the first importance, and its beginning has been auspicious. Pulmonary tuberculosis must be fought in the poor parts of large cities, and to carry on the warfare with any hope of success, the home and dispensary treatment must be initiated. This is the first and most essential step. The Phipps Institute has shown the way in this country, and it is not too much to say that every city of any size in this country should have one or more institutions of a similar character.

INSPECTING THE NEIGHBOR'S BACK YARD.

Every once in a while, when copy runs short, news is scarce, or some friend of the editor has an axe to grind or a sewer to dig, a newspaper sends a commission to some other city or country to look into its sanitary shortcomings and report on the same. These smelling committees are seldom, except by the merest accident, composed of men who know anything of the subjects of their investigation—but so much the better, for they are then without prejudice and their surprise and indignation at finding the conditions not perfect are not lessened by the knowledge that they never can be absolutely perfect, or by an acquaintance with similar or worse conditions at home.

One of these commissions—a committee of one, we believe—has for some months been taking notes of matters in this country for the edification of the readers of one of our English contemporaries. The commission—or, rather, commissioner—went first to St. Louis and disapproved of the World's Fair that happened to be going on at the time, and then wandered up to Chicago, which he didn't like at all. He was frightened the evening of his arrival by the dark streets and the tales he had heard of the hold-ups which, he was told, constituted one of the leading industries of that city; and the next day, before recovering his equanimity, he was taken to see the pride of the town—the stock yards. He didn't like them any better than he did the Pike at St. Louis, and sent a fearsome account of his visit to the journal which employed him. He says the health of the world is at the mercy of the unsanitary conditions prevailing there, and cries out for the erection of municipal slaughter houses to replace those owned and run by the trust. His state of mind is shown by the following passages selected from among many of similar tenor: "The whole nation should rise and insist upon the sweeping out of those truly Augean stables known as the Chicago stock yards." "The conditions of the Chicago packing industry affect the health of the entire world." "The conditions prevailing within this giant industry are almost inconceivable." "The larger death rate prevailing within the stock yards district is due to the conditions of employment and not to the dwellings of the workers." And so on.

We will leave the refutation of these denunciatory charges to the health authorities of Chicago, if they think it worth while, or to the packers. We have no doubt the Chicago stock yards are not as clean as a church or a theater, but what the commissioner expected to accomplish by such sensational and hysterical overstatements we fail to see. He probably had to justify his mission.

A somewhat similar comedy is being enacted in Cuba by some medical men—we would not dare call them sanitarians—sent there by one of the daily papers of this city. This commission is not unanimous as to the presence of yellow fever at Santiago, but one of the members is unanimous with himself in the belief that Havana ought to be a plague spot

instead of a city with a death-rate that should put to shame many of the most flourishing cities of the North. "Grave peril to life in Havana's foul sanitary condition," "How a fair surface covers a multitude of diseases," "Reeks with foul odors, and its whole subsoil is a feeding place for deadly germs," "The beautiful seashore that is a breeding place for death," etc., *ad nauseam* are the headlines that epitomize the sensational and absurd letters of this "sanitary commissioner." A little over two months ago the annual meeting of the American Public Health Association, a society of real sanitarians of Canada, Mexico, and the United States, was held in this "pest hole" with a phenomenally low death rate. The meeting was held there in response to the invitation of Dr. Carlos Finlay, Dr. Juán Guitéras, and other Cuban sanitary authorities, who did not shrink from exposing "Havana's foul sanitary condition" to these experts. That the conditions there were not perfect was evident to the visitors, but that a marvellous change had been effected in the few years since the island had been rescued from its age-long period of misrule was freely acknowledged by all. This was officially recognized in the following resolution: "The Association congratulates the civic authorities, the physicians, and the people of Havana in general upon the gratifying improvement made in its sanitary condition, and especially upon their work in freeing their beautiful city from any danger from that once dreaded scourge, yellow fever, by their persistent and skillful campaign against the yellow fever mosquito. We are especially gratified also that they do not propose to rest contented with what has been done, great as it is, but have already planned other sanitary improvements of great importance, including an efficient system of sewerage, which we wish them Godspeed in carrying out at the earliest practicable moment."

This is the deliberate and sober expression of opinion of a body composed of practical, up-to-date sanitarians, the leaders in this science of North America, and it is a sufficient refutation of the sensational report of a "sanitary commissioner," whose horror may be genuine, but whose sanitary views are of the last century. The health of Havana is in the keeping of practical and experienced officials, who are hampered in their work—as are sanitary authorities everywhere—by the meagerness of the appropriations allowed by unsympathetic and ignorant politicians, but who have accomplished and are daily accomplishing wonders. Let the cities of this country, north and south, keep —or, rather, make—themselves clean, and we shall have nothing to fear from Havana so long as such men as Finlay and Guitéras and their efficient aids are there to protect us.

New York's Dispensary System.

Advance sheets from the annual report of the Committee on Dispensaries of the State Board of Charities have just been received. The report contains matter of more than ordinary interest, when the fact is taken into consideration that the work of these dispensaries is more extensively carried on in this State than in any other part of the country, and that the dispensary system is more highly organized and developed here than in any other State. During the past year the Inspector of Dispensaries has made a special investigation as to the extent of compliance with the rules of the Board adopted pursuant to Chapter 368 of the laws of 1899, affecting the management of all licensed dispensaries. The result of this investigation goes to show that, as regards 24 of the 31 requirements of the dispensary rules, compliance is practically complete; that in four of those provisions compliance is fairly good, and that in three matters, viz., those requiring an investigation to be made as to the ability of doubtful applicants to pay for their treatment, the filing of results of these investigations, and the making of a minute, showing observance of the ordinances and orders of the Board of Health, compliance is somewhat lax. Almost all of the dispensaries seemed to be well managed. In only 34 of the 119 dispensaries examined was the work reported as being done superficially. Discrimination is exercised, more or less thoroughly, with regard to the admission of well-to-do applicants in all the dispensaries. In all but two of these institutions a matron is employed, while cleanliness and order are maintained in all but four. In only three dispensaries is the apothecary unlicensed or not a medical graduate, and the local ordinances of the Board of Health are strictly complied with. The report notes as an interesting fact that the facilities of but 28 dispensaries are used for the purpose of giving medical instruction, and in none of these is the treatment given the patient conditional upon his willingness to submit to an examination before a class. On the whole, it would appear that the dispensaries of New York State are in a satisfactory condition, considered from all standpoints.

Army Ambulances.

Sir Frederick Treves in his testimony given before the British Royal Commission on the Boer war, especially condemned the English army ambulance. He went so far as to say that an English ambulance is hardly fit to transport the sick, for it is almost impossible for a well man to sit in it when it is moving rapidly. If one wants a wagon that can be driven at a trot over a series of walls, or practically over churchyards, and that will come out unbroken, the English ambulance will do it, but it is a rough affair. Major T. P. Jones, R. A. M. C., writing in the *Journal* of the corps for February, says, on the other hand, that the ambulance wagons used in the British army are most useful vehicles and well adapted for their purpose. Most writers on the subject, however, agree with Treves, and the objection that in these wagons comfort has been sacrificed to strength is considered valid. The American army ambulance cart, so well described by Munson in his work on "Military Hygiene," is undoubtedly the best in the world. It is light, strong and comfortable. Strength is, of course, an essential feature in such vehicles, but it is by no means the only essential feature. Of what practical use is an ambulance, which, although it does not itself break, so jolts and shakes its unfortunate passengers that it is death or loss of limb to those seriously wounded? It would undoubtedly be a wise step on the part of the British war authorities if they were to adopt the model of the American army ambulance.

Something Accomplished After Forty.

In his now celebrated valedictory address, in the section dealing with "the comparative uselessness of men above forty years of age," Osler said: "Take the sum of human achievement in action, in science, in art, in literature—subtract the work of the men above forty, and, while we should miss

great treasures, even priceless treasures, we would practically be where we are to-day." Six years ago, when the late Major Walter Reed began the experiments by which he demonstrated to the satisfaction of the scientific world the correctness of Finlay's theory regarding the rôle of the mosquito in the propagation of yellow fever, he was forty-eight years old. Five years ago, when Major William C. Gorgas, acting upon this theory, drove yellow fever from Havana and freed the Southern States from its menace, he was forty-six years old. Without the achievement of these two "comparatively useless" men, would we practically be where we are to-day?

News of the Week.

New Requirements for Degrees at Columbia.—A most radical change in the programme of studies leading to the degrees of A.B. and B.S., to take effect July 1 of this year, has been announced by the secretary of Columbia University. Candidates for the degree of bachelor of science will not be required to offer any ancient language at entrance or to pursue the study of any ancient language in college. The effect of this step will be that men who wish to enter the school of applied science, law, or medicine may get both a college degree and a professional degree in six years. The standard of attainment of the degrees of A.B. and B.S. will not be fixed in terms of years of college residence, but in terms of work accomplished. A total number of 124 points—a point being given for the satisfactory completion of work requiring attendance of one hour a week for one half-year—will be the requisite for graduation. Students will be admitted to the freshman class hereafter in February as well as September. When 72 points of the 124 required for a scholastic degree have been won, students may under certain restrictions enter on the work of the School of Applied Science, the College of Physicians and Surgeons, the Teachers' College, or the School of Fine Arts, and receive the scholastic degree on completion of two years' work of the professional course.

Society of Medical Inspectors.—A society for the study and discussion of problems in hygiene and public health was organized by the medical inspectors of the Department of Health of the City of New York, at a meeting held at the Academy of Medicine on March 3, 1905. Inspectors in the various divisions of the department and in the various boroughs are eligible to membership in the new society, which will hold monthly meetings at which papers will be read and discussed by members, and addresses delivered by the higher officers of the department and other specially invited sanitarians of repute. Good fellowship will be promoted by means of annual dinners, etc. At the first meeting, which was well attended, Dr. Edward M. Thompson, Chairman of the Committee on Organization, presided. A constitution was adopted and the following were elected officers for the ensuing year: *President,* Dr. Augustus C. McGuire; *Vice-President,* Dr. Otto Jahn; *Secretary,* Dr. Edward M. Thompson; *Treasurer,* Dr. Leopold Marcus; *Executive Committee*: Drs. Joseph Baum (Chairman), Helen Knight, Samuel A. Buchenholz, Thomas A. Neafsey, and DeSantos Saxe.

Bills of Medical Interest Introduced in the Illinois Legislature.—Senate Bill No. 171, revising the present medical practice act, and providing for the regulation of regular, homeopathic, eclectic, physiomedical, and osteopathic practice, is being considered by the Committee on License and Miscellany. Senate Bill No. 225, for an act to establish a State Board of Examiners of Registered Nurses, and Senate Bill 226, for an act to regulate the practice of dental surgery, have been approved by the committees to which they were referred. A bill providing for the appointment on the State Board of Health of two regulars, one homeopathic, one eclectic, one physiomedical, and one osteopathic member, has been favorably reported on by the Committee on Judiciary Department and Practice. A bill has been introduced by a member of the Legislature, making it the duty of the State Board of Health to see that diphtheria antitoxin be kept in each county seat in the State for sale to physicians, and that supplies be furnished to the poor free of charge on the order of the overseer of the poor. This bill has received the endorsement of the State Board of Health.

The Plague.—In India during the week ending March 4, there were 34,000 deaths from bubonic plague; in 1903 the mortality from the disease was 850,000, and since the beginning of the present outbreak 3,000,000 persons have died from this cause. The infection recently spread to Burma, where it is making rapid strides. This season of the year always favors its spread. The Indian Government is making every effort to eradicate it, burning whole sections of towns and segregating the inhabitants. But, owing to the climate and the unsanitary condition of the outlying districts and native sections of the towns, it is difficult to cope with the epidemic, which breaks out continually at fresh points. The deaths are said to average 90 per cent. of those infected. In South America, also, the disease is reported to be increasing, a true epidemic having raged for some time in Pisagua, Chile. A recent telegram to *The Herald* says that, according to the Health Board reports, up to March 3 there have been 103 fatal cases of plague in that town. There is no serum, either curative or prophylactic, to be had, and no disinfectants, and the situation is regarded as extremely critical. Not more than five hundred inhabitants remain in the city. Twelve new cases were reported on March 10, of which five were fatal. There are 136 patients in the Lazaretto. Pisagua now has only one doctor attending the patients, two others being ill.

Cancer Views.—At a recent meeting of the Berliner medizinische Gesellschaft an animated discussion on the nature of cancer took place between von Leyden on one side and Orth and von Hansmann on the other. Leyden held that the neoplasms were of parasitic origin and claimed that this had been absolutely demonstrated. Orth and Hansmann, on the other hand, denied with equal positiveness that cancer was either parasitic or contagious. They further held that it occurred with no greater frequency now than in former years, the seeming increase in the number of cases being due simply to the fact that the disease is more easily recognized now. The same difference of opinion exists in this country between the Boston and the Buffalo investigators.

The Surgeon Lost His Glasses.—The Paris correspondent of *The Herald* says that an American woman was recently operated upon in Paris with startling results. She underwent a laparotomy in America, but her health was not improved and she was operated on a second time in Germany. Again she received little or no benefit, and finally she had an operation in Paris, where the surgon took out of the abdominal cavity a pair of gold-rimmed pincenez. The patient has now recovered her health, and has instituted an investigation to determine whether the glasses should be returned to the American or the German surgeon. The German surgeon is in an

embarrassing position in any case, for either he left the glasses in the abdomen or he failed to find them when he operated.

Street Cars and the Health Board in Cleveland.—Dr. Friedrich of the Health Department of Cleveland recently started a crusade against dirty street cars, and his deputies are busy inspecting the sanitary condition of the cars on the several lines. The health officer ordered that the cars be scrubbed at certain times and a standard of cleanliness necessary to health maintained. One day last week one of the lines was tied up for two hours because a motorman and conductor attempted to take out a street car that did not meet the standard of cleanliness which the city health officer is putting in force. It was stopped by agents of the board. The Health Board is now considering an ordinance to limit the number of passengers that each car shall be permitted to carry.

Dayton, Ohio, Health Report.—The report of the Health Department for 1904 is as follows: Total number of births, 2,012; total number of deaths, 1,308, the death rate being thirteen to the thousand of the population. The following were the contagious diseases reported to the Board: Smallpox, 176 cases, 22 deaths; measles, 278 cases, 1 death; scarlet fever, 64 cases, 3 deaths; diphtheria, 54 cases, 5 deaths; chickenpox, 49 cases, no deaths; typhoid fever, 27 cases, 17 deaths; tuberculosis, 176 deaths. The smallpox cases were unusually severe and death-rate high.

Precautions Against Yellow Fever on the Isthmus.—Gen. Davis, Governor of the Panama Canal zone, has notified the Secretary of War that he can dispense with nearly all of the marines on the isthmus, on account of the fear of an epidemic of yellow fever in the locality where the marines are stationed. The Secretary of the Navy has been called upon to order all of the marines North, except about one hundred. They will probably be sent to Guantanamo.

Cincinnati Academy of Medicine.—At a regular meeting on March 6, the following officers were elected for the ensuing year: *President,* Dr. Magnus Tate, Covington; *Vice-presidents,* Drs. Robert Carothers and Alfred Gaither; *Secretary,* Dr. Stephen Cone; *Treasurer,* Dr. A. G. Drury; *Censor,* Dr. E. G. Zinke; *Trustees,* Drs. Dandridge, Heady, and Isham. The installation of the new officers took place on the evening of March 13.

Tri-State Medical Association.—At the seventh annual session of the Tri-State Medical Association of the Carolinas and Virginia, held at Greensboro, N. C., on February 28, the following officers were elected: *President,* Dr. Hubert A. Royster of Raleigh, N. C.; *Vice-presidents,* Drs. Hugh M. Taylor of Richmond, for Virginia, C. J. W. Jervey of Greenville, for South Carolina, Albert Anderson of Wilson, for North Carolina; *Secreatry,* Dr. Rolfe E. Hughes of Laurens, S. C.; *Members of the Executive Council,* Drs. W. W. McKenzie of Salisbury, N. C., O. D. Wilson of Spartansburg, S. C., and G. D. Upsher of Richmond, Va. The next annual meeting will be held at White Stone Lithia Springs, S. C.

Infectious Disease Inquiry.—An appropriation of $35,000 has been made by the Board of Aldermen to permit Health Commissioner Darlington to make a census and inspection of the congested distrists for the purpose of obtaining data to aid in decreasing infectious diseases in tenements.

Incorporation of the American Medical Association.—The bill introduced in the late Congress to secure national incorporation of the American Medical Association, after being variously and unsatisfactorily amended in both the Senate and the House judiciary committees, failed of passage in any shape, owing to the press of what was regarded by Congress as more important business.

Dr. Wm. Muhlberg, professor of physiology at the Medical College of Ohio, has resigned because of ill health, and his resignation has been accepted.

Obituary Notes.—Dr. James A. Moore of New Haven died on March 11 of cerebrospinal meningitis. He was a graduate of the Yale Medical School in the class of 1894.

Dr. Albert B. Prescott, the oldest professor in the University of Michigan, died on February 25 after a prolonged illness. He was born in New York State in 1832, and had been a member of the faculty of the University for forty years. He was the author of several standard works on organic chemistry and chemical analysis.

Dr. Michael Peters died at Owasso, Mich., on February 25, at the age of 35 years. He was a native of Canada, and was graduated from the Detroit Medical College in 1894.

Dr. George R. Metcalf of St. Paul, Minn., died suddenly at Orvieto, Italy, on March 1. He was 57 years old, and was born at Brattleboro, Vt. He was graduated from Amherst College and then entered the Medical Department at Columbia University, graduating in 1874. Dr. Metcalf had practiced for many years in New York before going to St. Paul, twenty-four years ago.

Dr. Henry F. Barnes died in Indianapolis on March 2 from the result of injuries received in a fall from a street car. He was born in Orleans, Ind., and was graduated from the Jefferson Medical College in 1854. From 1856 to 1862 he was assistant superintendent of the Indiana Central Hospital for the Insane. He served for a time as surgeon of volunteers during the Civil War, and for five years after the close of the war practised medicine in Louisville, Ky., subsequently moving to Indianapolis.

Dr. Norborne C. Lewis of Lawrenceville, Va., died March 2 after a long illness, at the age of 56 years. He was a graduate of the New York University Medical School in the class of 1869.

Dr. J. Austin Miller, formerly of Oakland, Cal., died at Houston, Tex., on February 24, at the age of 47 years. He was a graduate of the Louisville, Ky., School of Medicine in the class of 1885.

Dr. Samuel McGill of Schuyler, Va., died on March 2 of acute nephritis. He was a graduate of the Medical Department of the University of Virginia in the class of 1864.

Dr. A. B. Craig died at Philadelphia on March 15 from epidemic cerebrospinal fever acquired through attendance upon a patient suffering from the same disease. Dr. Craig was 33 years old and was a graduate of the Jefferson Medical College.

Dr. Thomas E. Edwards of Memphis died at Union City, Tenn., on February 27, after a prolonged illness. He was born near Union City, and was a graduate of the Medical Department of Vanderbilt University, Nashville, in 1882, and of the Medical Department of the University of Tennessee in 1883.

Dr. James N. Cassidy died at his home in Sharon Center, O., on March 3, at the age of 60 years. He was a graduate of the Medical Department of the University of Wooster, Cleveland, in the class of 1869.

Dr. Joseph Schmitz of this city died on March 8 at the age of 53 years. He was a graduate of the University of Würzburg in 1878.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

DR. KLEIN'S [illegible] SPIFALS AND [illegible], [illegible] TENOSIS AND MURMURS—ACCESS BY THAYER IN [illegible] THROMBOSIS—ANURIA FROM CALCULUS—MIDWIVES' BOARD—AFTER-CARE ASSOCIATION—UNIVERSITY—THE LATE DR. THOMSON OF GLASGOW.

LONDON, February 24, 1905.

A PRELIMINARY report respecting oysters and typhoid was issued yesterday, giving the results of experiments undertaken by Dr. Klein at the request of the Fishmongers' Company.

Six series of experiments were carried out to determine the behavior of the bacillus of typhoid in oysters, cockles, and mussels, when they were directly infected with a definite quantity of the microbe; or when they were kept 24 hours in sea water which had been previously infected with a definite quantity. Professor Klein concludes that oysters readily take up into their interior the bacillus, whether introduced into the shell or the surrounding sea water; those clean at starting rapidly clear themselves from the microbe if kept in clean sea water frequently changed. Kept out of water they clear themselves to a less extent and more slowly. Oysters from a polluted locality clear themselves much more slowly, even if kept in clean water, and much more slowly still if kept out of water. Prof. Klein considers that the process of cleaning cannot be merely passing out the bacillus, but must be largely due to a power in the oyster to devitalise the microbe. This was shown by experiments with those kept out of water, and is evident also from the rapidity with which the microbe disappeared from those kept in clean water compared with the small number found at the same time in the surrounding water. Infected oysters kept out of water until practically clean, if subjected to reinfection were less able to deal with the microbe, even if kept in clean water, than others similarly treated but kept in clean water all along. The *Bacillus coli* was found to be rapidly destroyed by the oyster; so that when present it must be derived from the surroundings. Oysters give no sign to the eye of being infected, except those from a polluted locality, [illegible]

Cockles readily embody the bacillus, the number trebling after being removed 5 days from infected water and kept in clean sand. Mussels appear to embody the microbe to a greater extent than oysters and cockles.

The report of the committee to inquire into the relations of hospitals and medical schools on behalf of the Prince of Wales as President of the King's Fund was issued last Saturday. It is just such a document as was to be expected. It will certainly fail to satisfy the antivivisection agitators, while it vindicates the hospitals from the most important charges made against them. As to the first [illegible] given directly or indirectly towards the maintainance [illegible] education, the committee say it is impossible to answer, as in several cases the hospitals and schools were founded together, and both were the object of the founders' bounty, while in other cases the hospital was founded by the school; school buildings were provided by money subscribed for that purpose; in other cases sums had been contributed to hospitals after their foundation, part of which, to the [illegible] money given to King's College or University College hospitals in 1903 went to the schools. In Guys and the Royal Free hospitals the committee doubt whether the schools can be considered to derive benefit. The other hospitals made contributions either directly or indirectly. As to the second question, whether the hospitals receive any return for such benefits, the committee find that the body of students and practitioners educated in a hospital diffuses a wide interest in it, and tends to aid its finances, that the presence of the students watching their teacher keeps him on the alert, that the opportunity for teaching attracts the gratuitous services of the most eminent men in the profession, and the publicity of the work helps to maintain it at a high level.

It was urged before the committee that the great amount of work done by students constituted a pecuniary advantage to the hospitals, but they found expenses at hospitals with schools exceeded those without, on which account they are of opinion that there is no saving from the presence of students, and indeed they suggest that it is questionable whether there is not extravagance in some of the hospitals having schools attached. They do not doubt that a school tends to give the hospital a progressive character, though it also tends to place the administration under the control of the staff, and so to increase expense through the advances of medical and surgical science. No categorical reply is possible to the question whether hospitals receive an equivalent benefit from their schools for contributions made. The committee's conclusion is that the benefits are mutual and may fairly be set off one against the other. Finally the committee state that it is impossible to ascertain the intentions of the original founders, or the exact motives of subsequent donors, and the complexity of the relations between hospitals and schools renders it undesirable, even if possible, to open up their past transactions. But for the future the committee submit that the distinction between hospital and school in every case should be drawn so clearly that the general public may understand it, so that no question may arise as to the destination and application of money contributed, whether by the King's Fund or from any other source.

A case of soft-valve mitral stenosis without a murmur being heard during the two months the patient was in hospital, was reported to the Clinical Society by Dr. Ewart. The heart was shown, enlarged and flabby, the other valves competent. The mitral was orifice-narrowed, but there was hardly any induration. The term "soft-valve stenosis" described well enough a lesion in which the early fibrous changes did not develop into progressive thickening and induration. The action of a soft stenosed valve must differ from that of the rigid stenosis, particularly when, as in this case, the chordæ tendineæ and papillary muscles were free from stiffness, shortening, or fibrosis.

Dr. Seymour Taylor did not think the softness alone would account for absence of murmur, and suggested the absence of the proper auricular driving force. He thought mitral stenosis the most interesting of cardiac diseases. Its frequency, since Gairdner's paper, was generally recognized, but its mode of production was still unsettled. Valvulitis was generally due to rheumatism or chorea before puberty through which the valve did not keep pace in development with the rest of the heart. After puberty the consequence was commonly incompetence, rarely stenosis. Dr. P. Weber mentioned a case of hard stenosis with the ring partly calcified, in which the murmur disappeared for a time before death. Dr. Pasteur asked what change of rhythm or in the character of the first sound was suggestive of stenosis. Dr. W. E. Wynter thought the thinness and softness of the valve partly explained the absence of murmur. He had not met with mitral stenosis under 7, and rarely under 14 years of age. But he agreed that persistent infantile size of the ring gave rise to stenosis. The history of rheumatism was often difficult to obtain; arthritis might be absent in children. Perhaps in Dr. Ewart's case there had been one attack of a slight degree. Dr. Hawkins mentioned a case of sudden death from thrombosis of the abdominal aorta. Mitral stenosis was also found post-mortem, but no murmur had been noticed during a month's treatment in hospital. Dr. F. Taylor (President) agreed that the softness was not enough to account for absence of murmur, and he pointed out that the left auricle did not seem hypertrophied.

At the same meeting Mr. Percy Paton described a case of accessory thyroid in the right submaxillary triangle, which could be felt both inside and outside the mouth. The diagnosis was uncertain, but the patient (a girl of 16) was sure it was growing fast. On removal it was found to be composed of thyroid tissue. Mr. Spencer referred to the work of the late Professor His, and showed an illustration which he thought might explain the presence of thyroid tissue in the position in which Mr. Paton found it. He suggested that it was desirable to know that there was other thyroid tissue in the body before removing it all. Mr. Paton replied that partial removal would probably result in recurrence, and hemorrhage was often profuse from operations on thyroid tissue.

Mr. Betham Robinson then described a case of extra-peritoneal ureterolithotomy in a child of 3. Comparing it with two cases in adults he found the operation easier in the child on account of the small amount of fat in the abdominal wall and sub-peritoneal connective tissue, the shallow pelvis, and the abdominal position of the bladder.

Mr. Drew described a case of anuria from calculus in a boy of 4. Stones at different dates had been removed from the bladder, urethra, left ureter and kidney. Diagnosis was difficult, radiography negative. There were no symptoms referring to the right side, but after death a stone was found blocking the right ureter at its lower end. Mr. Paton mentioned a case of death in which no urinary symptoms had occurred, but a stone was found at the post mortem in one ureter.

The Midwives' Board is beginning to reap some of the seed it has scattered, and is dissatisfied with its crop. Sir Wm. Sinclair, the only member with clear views worthy of a medical man, looks forward to the Board's continuing its present policy until it makes a case for amendment of the act unanswerable.

It may be noted at the same time that the act is producing dissatisfaction among the female population who were declared to be all in favor of it. A cry is raised from rural districts that the new regime is only fit for towns.

It is declared impossible to supply villages and hamlets with registered midwives, and the abolition of the old neighborly help "as old as the villages themselves" and older too, will lead to much distress. Those who have helped their neighbors can easily register, it is said. But the objectors say no, they cannot or will not, and if they did it would only perpetuate under a false pretence the old voluntary system.

The After-care Association for poor persons discharged as recovered from lunatic asylums endeavors to meet their wants as to homes, clothes, and necessities. The annual meeting was held on Wednesday, when it was stated that the income had advanced from £648 to £818, but much more is required, for of the 7,000 persons discharged annually the majority are poor and friendless.

At the annual meeting of members of the University College on Wednesday the resolution for the incorporation of the College with the University of London was agreed to. The Incorporation has now only to run the gauntlet of parliament as an unopposed measure. The new Medical School provided for by Sir D. Currie will be built adjoining the Hospital provided by the late Sir B. Maple.

The Glasgow school has lost an enthusiastic and favorite teacher in Rob. S. Thomson, M.D., F.R.S. Ed., Professor of Medicine in Anderson's College, who has died at the early age of 47. In 1901 the University conferred on him the degree of D. Sc. During about twenty years of his too short career he held a number of appointments and devoted much attention to teaching. He was for many years visiting physician to the Smallpox Hospital, and among numerous contributions to the journals and societies were some on questions connected with that disease.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

NECESSITY OF GREATER HOSPITAL ACCOMMODATIONS—NEW MEDICAL SOCIETIES—NEW METHOD OF CARDIAC PERCUSSION—THE FINSEN TREATMENT OF SYPHILIS—THE FINSEN TREATMENT OF LUPUS.

BERLIN, March, 4, 1905.

At nearly every session of the city council the question of hospital accommodation comes up for discussion. Weyl, the eminent hygienist and also a member of parliament, recently communicated the fact that 220 lodge members who were in need of hospital treatment could not be accommodated in the crowded Berlin hospitals. Kürschner declares that this unfortunate state of affairs will soon be offset by the opening of the great Rudolf-Virchow Krankenhaus, with its 2,000 beds. This present condition is due partly to the decrease in the number of beds at the Charité Hospital. It should be remembered that in such emergencies, when the hospitals are overcrowded, barracks should be held in readiness for patients. I hope soon to have a report to make on measures adopted by our city government on this question.

It becomes more and more difficult to keep in touch with all of the new societies which have a certain relation to medical science. On the sixteenth of February, a society called "Gesellschaft für Medicin, Hygiene, und Medicinalstatistik" was incorporated. This society intends to work on the questions of political economy and medicine. Of the greatest importance are the subjects of workingmen's insurance bills, occupation diseases, alcoholic abuse, care of infants, infectious diseases, municipal sanitation, and the improvement of dwellings. On all of these subjects the results of the investigations of both physicians and political economists are to be collected, the problems being attacked from a purely scientific point of view. This society opened with a roll of ninety distinguished names, which portends a favorable outlook for its usefulness.

A topic of the greatest interest to the general practitioner was treated early in the year by Goldscheider in the "Verein für innere Medicin," under the title "Uber Herzpercussion." The speaker has made use of the Röntgen rays according to the method of Moritz. He found the old question as to whether the absolute or relative dullness is better determined by percussion, to be in favor of the relative, which gives the correct limits of the heart. But this must be determined by only very low percussion. The Röntgen rays also reveal the enormous influence of respiration on the position of the heart. Therefore the following directions should be observed. The last cardiac limit in deep inspiration; the right and the upper cardiac limit in deep expiration. The lower part of the right heart and the great vessels must be examined in deep expiration. Turban and Rosenbach as well as Goldscheider find that very low percussion gives the best results. There must be absolute stillness in the examining room and the sound should be heard by the examining ear only. A second factor of great importance is "sagittal percussion," which means that which is practised from before backward. Transverse percussion gives incorrect results. In percussing, the intercostal spaces only must be made use of. The speaker, in concluding, stated that Turban, Rosenbach, Petersen, and others have also accentuated the importance of low percussion, although their opinion has not always been accepted. However, these researches put an end to all opposition, for the Röntgen rays prove that these limits are determined in an exact mathematical manner.

At the "Verein für innere Medicin," which met on the twenty-third, Ziehen read a paper entitled "Ueber psychische Begleitsymptome bei Lues Cerebri." Four kind of syphilis of the brain are enumerated: 1. Disease of the vessels. 2. Gumma of the brain. 3. Gummatous infiltration of the cerebral membranes with extension to the brain. 4. Dementia paralytica. The speaker confined his attention to the discussion of the first class. He found besides large hemorrhages, perivascular and endovascular alterations. The clinical picture resembles that of dementia paralytica, although the mental activity is not impaired so extensively. The most marked clinical symptoms are the acute onset with deep stupor very similar to that of an infectious disease; when this stupor lasts for more than eight days, syphilis of the brain is suggested; hallucinations of the muscle-sense, the patient believing that he is rolled about and raised in the air, and an acute loss of memory for recent events. The acute cases offer a good prognosis, especially when they have energetic specific treatment. The insanities of chronic syphilis are characterized by poisoning and persecution manias, increased weakness, and irritability. These conditions require the ordinary treatment of nervous diseases and do not yield to treatment by mercury and potassium iodide.

Lesser's paper, read at the medical society on January 11, is of great value on account of the large number of cases of lupus which he has treated by the Finsen method. This treatment is only ten years old, and on account of the fact that lupus is extremely prone to recur, great precaution should be used in publishing results. Of the 800 patients treated by the Finsen method, 40 per cent. to 51 per cent. were cured, 121 remained without recurrences for from two to six years. The cosmetic effect was excellent, corresponding to the elective effect of the light which acts on the tissue of the neoplasm only, and not on the normal tissue. The Finsen method is superior to all others—the sharp spoon, caustics, excision, transplantation, tuberculin and hot air. The limitation of the Finsen treatment is seen in the case of deep lupus ulcers. In the discussion which followed the reading of Lesser's paper, all kinds of treatment were mentioned. Liebrich spoke in favor of the combination of cantharidin and the Finsen light treatment. Holländer emphasized the fact that the affection of the mucosa cannot be influenced by the Finsen rays, and also that in 60 per cent. of all cases the first appearance of the disease is in the nasal cavities. This is the dominion of the surgeon, and the hot-air treatment is indicated. The best results are due to the combination of the Finsen rays and the hot-air treatment. His cured cases have been followed for nine years. Blaschko and Senator spoke of the good results of the tuberculin treatment.

THE JAPANESE HOSPITAL SHIPS.

(From Our Special Correspondent.)

KOBE, JAPAN, January 15, 1905.

In medicine as well as in the other arts and sciences, the Japanese seem to have shown the same ability to appropriate for their own use all those things which have been found to be of service by Europe or America. Among other things may be mentioned the hospital ship, which has been extensively used during the present war. A description of one of these may prove of interest.

The *Kobe Maru*, which is at present anchored in the harbor of Kobe, is a fair type of this class of vessel. On approaching the vessel it is seen that she is painted white, with a broad band of green about two feet wide which extends completely around the hull of the vessel about midway between the rail and the water line. A large Geneva cross is painted on each side of the smokestack. With these characteristic distinguishing marks the vessel should be assured of not being mistaken for a combatant vessel or a merchantman. Arriving on board, it is found that the vessel is a fairly modern steamer of about 3,000 tons, which by a few changes has been converted into a hospital ship. The vessel was formerly in the passenger service of the Nippur Yusen Kaisha Company. The sick are all quartered upon the deck. The privates are placed in suitable sized compartments in bunks, which are three tiers high. The total capacity is 180. For the sick officers the ordinary staterooms are used. The bunks are constructed of iron and furnished with good springs and mattresses.

The amount of air space per capita appears to be inade-

quate, but this is compensated for in a way by the ordinary ship ventilators. No forced draught or other mechanical means of changing the air is used. Of course, it is proper to take into consideration that the distances to be run are not very great, at most not over three days, and no doubt during the majority of the voyages the weather conditions would be such that the portholes could be kept open, and thus a supply of fresh air assured. A neat operating room, furnished with modern furniture, is located on the same deck. The number and kind of surgical instruments is sufficient to perform almost any operation. The sterilizers are connected with the ship's steam supply, thus obviating the necessity of a separate heating apparatus. The room receives excellent light from an overhead skylight. A dark room is especially fitted up for *x*-ray work, for which there is a good machine on board. An isolation hospital for contagious cases is fitted up on the deck below that used for regular hospital purposes.

No female attendants of any kind are employed on board. The Japanese medical men do not seem to be very favorably impressed with female nurses for army or navy purposes. Six medical officers are assigned to each vessel of like capacity. All friction is avoided by the senior medical officer being in absolute charge of the vessel in all matters except the actual sailing of the vessel. The medical officer simply orders the master of the ship to proceed to such ports as he may desire, which orders must be carried into effect at the earliest practicable moment.

The sanitary arrangements are very good, all sinks, closets, etc., being of modern design, and they generally bear the name of some foreign maker. Everything is kept scrupulously clean, and from all appearances it would seem that the vessels are well managed. The principal work of the vessel has been to carry sick and wounded soldiers and sailors from the neighborhood of Port Arthur to Osaka and other base hospitals.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 9, 1905.

Dangers from the "X-Ray Atmosphere" to the Operator; their Prevention.—H. W. Van Allen calls attention to the dangers attending *x*-ray work, with special reference to the effects on the testicles. Out of seven patients who had undergone treatment in this region, spermatozoa were absent in four. A somewhat prolonged course of exposures seems necessary to effect this result. The sexual organ does not seem to be impaired. Other untoward effects often show themselves in the skin and its appendages. The nails and hair are brittle and of slow growth. The skin itself is dry and of a yellowish hue so peculiar that it is almost characteristic. Many have dry seborrhea. Indigestion is present, especially of the intestinal kind. These men complain of lack of ability to concentrate their thoughts for any length of time and are drowsy although many suffer from inability to have continuous restful sleep at night. The disposition is somewhat irritable. These operators complain of an unnatural sensation of cold. Radiographs in some instances of the thinner parts of the body show a premature sclerotic condition of the arteries. To prevent these results the author describes an arrangement of the ray apparatus, the latter except the tube being in one room, while the tube and couch for the patient are in a room adjoining. The wall between the two rooms should be covered with a thin layer of sheet lead, and have a peep-hole through which to judge the tube. This plan does away with fluoroscopy, but the author regards this as a treacherous method in that it leads to unwarranted conclusions.

New York Medical Journal, March 11, 1905.

An Unusually Severe Case of Chorea Successfully Treated with Apomorphine.—The patient of M. G. Tull was a girl of fifteen years. The usual remedies, including arsenic, were given without avail, and finally apomorphine 1/40 gr. was injected hypodermically. Within probably three minutes the incessant motion had ceased, the muscles were relaxed, and the child slept peacefully and quietly. The author ordered 1/20 gr. by the mouth every three hours with the arsenic continued as before. At no time was there sign of nausea or vomiting. The result was all that could be desired; a steady, gradual improvement with no return of the severer symptoms. Ten days later the patient was able to go to the seashore where she remained entirely well.

Remarks on the Results of X-Ray Treatment in Several Cases of Carcinoma of the Uterus.—A series of cases reported by S. Tousey. In one case treatment seemed to prolong life for a year. A second case was not at all benefited, the disease being far advanced. In a third case the discharge and size of the growth were kept down, the general condition improved, and a fair state of comfort maintained for nearly a year; case still under treatment. In a fourth case the patient's strength improved and the discharge practically ceased; the case still under treatment; outlook unfavorable. In a fifth case results have been promising but there has been no distinct cure. The author describes in full the various modifications of apparatus as used by him in the several cases. These are not selected, he says, as an argument in favor of the *x*-ray in the treatment of inoperable or recurrent carcinoma of the uterus, but rather as showing fairly what may be expected from it in the various stages, and types of the disease. He strongly recommends the adoption of the treatment at any stage before the recurrent cancer has too far sapped the patient's vitality.

Medical News, March 11, 1905.

Uric Acid—Its Influence on Gout.— C. C. Ransom reviews the various theories of the relation of uric acid to gout, and notes that the ideas of Horbaczewski are generally accepted to-day under the designation of the nuclein theory which maintains that there is no relationship between urea and uric acid, the former being the terminal product of proteid metabolism, the latter being derived exclusively from the nuclein of the cell. The nucleo-proteid of the cell is broken up, the proteid part undergoing the usual proteolytic changes is converted into urea. The nuclein molecule is oxidized into nucleic acid. The nucleic acid, being further oxidized, forms on the one hand phosphoric acid and on the other the so-called "mother substance." The mother substance is oxidized into uric acid on the one hand and the purin xanthine or aloxur bases on the other. There is no longer a belief that uric acid is toxic *per se*, for in diseases in which it is present in excess, it presents no specific symptoms. Again, it has been shown that excess formalin holding food with a corresponding output of uric acid causes no disturbance. Gouty attacks are generally preceded by gastrointestinal disturbances, and during the attack the acid output is increased. Following the attack there is always a diminished amount excreted, following the regeneration of the tissue. This idea is quite consistent with the condition of affairs about the joint, and taken in connection with the nuclein theory as to the origin of uric acid, will explain the phenomena which take place in the infection of the joint. Through this trauma a slight inflammatory reaction is set up in the joint structure. The toxic material at once begins its action upon this susceptible tissue. The leucocytes, in the effort to destroy the toxins in this process, come to the joint structures in great number; unable to cope successfully with the toxin, they are destroyed. The nuclein of the cell is oxidized into uric acid, and the result is the gouty joint.

American Medicine, March 11, 1905.

Advances in the Physiology and Pathology of the Pancreas and Their Application to the Diagnosis of Pancreatic Diseases.—John C. Hemmeter in a lengthy article fully considers this subject. Of special interest are his observations concerning the diagnosis of relative pancreatic insufficiency from defective protolysis, amyolysis, and adipolysis. He believes the effort to determine the degree to which protolysis is interfered with is rendered futile by the presence of erepsin, secreted in the intestinal juice, and which can break down proteids very rapidly after they are once attacked by gastric juice. Defective fat digestion as a gauge for pancreatic insufficiency is equally disappointing. However, he believes great aid can be obtained from the method of Aloph Schmidt. This is based upon the physiologic fact that only gastric juice can digest connective tissue (collagen), and only pancreatic juice can digest the nuclear substance of meat fiber. Hence the presence of remnants of undigested connective tissue in the feces indicates insufficiency or absence of gastric secretion and the presence of nuclei in the cells of meat fibers points to insufficient pancreatic secretion. Hemmeter tested the stools of two patients, one suffering from pancreatic cyst, comprising the duct of Wirsung and the other from a stenosis of the duct, caused by an old pericholecystitis. In both cases the stools contained muscle fibers, showing well-preserved nuclei.

Uterine Fibroid Tumors.—J. Clarence Webster bases his conclusions on a study of a series of 210 cases treated surgically. He says widely held views as to the comparative harmlessness of uterine fibroids should be greatly modified. Taking into consideration the pressure effects, the tumor degenerations, the pelvic and abdominal complications, the changes in the heart, large vessels, kidneys, and liver, the chronic anemia of hemorrhagic cases, and other occasional associations, *e.g.* suppuration, gangrene, peritonitis, phlebitis, embolism, the influence of pregnancy and labor, the new growths must be considered as seriously increasing morbidity and mortality in women in whom they

occur. Owing to improvements in technic and to careful preparation of patients, splendid results have been obtained from operative procedures, and the mortality has been greatly reduced. All large or growing tumors or small ones, which cause troublesome or serious symptoms, should be treated surgically.

Tuberculosis of the Gastrointestinal Tract.—J. A. Lichty reports a case of perforation and partial stenosis of the bowels. The patient had been closely associated for five years with a sister who died of pulmonary tuberculosis. Following a severe attack of pneumonia, she was troubled with a hacking cough, with much gas in the bowels and with constipation. Later, there were alternating attacks of constipation and diarrhea, and it was impossible to regulate the bowels. Laxatives or enemas caused unbearable pain. She had severe night sweats and a poor appetite. Temperature 102° to 103° every evening; normal every morning. She had a hectice flush and was slightly emaciated. There was marked tenderness over the descending colon, and a tender mass could be felt near the splenic flexure. No albumin in the urine; no leucocytosis. The lungs were negative except for a patch of dullness with distant breath sounds and diminished fremitus to the left of the heart. A few tubercle bacilli were finally found in the sputum. Pain in the abdomen continued to get worse, becoming sharp in character to the right of the umbilicus; there was marked rigidity of the abdominal muscles and a condition of collapse ensued. The autopsy showed a large ulcer at the splenic flexure, which part of the bowel was much thickened and constricted by Nature's attempt at healing. Tubercle bacilli were found in the base of the ulcer. In the ileum were many ulcers characteristic of tuberculosis, one of which had perforated. In the apex of the right lung were a few cheesy nodules, and the pleura of the left lung was much thickened. Primary tuberculosis of the intestine is a very rare condition, and this case comes very close to such an infection. The author discusses the distribution and frequency of tuberculous lesions in the various portions of the alimentary canal, and touches upon the transmissibility of bovine and human tuberculosis. He cites a case in his own experience, which goes to prove their identity. A farmer's healthy daughter evidently contracted pulmonary tuberculosis by drinking the milk of a tuberculous cow. The details are given, and the case is very convincing.

Etiology and Treatment of Acute and Chronic Rheumatism.—G. Morton Illman says it is necessary to investigate promptly and carefully all gastrointestinal conditions occurring previous to or associated with rheumatism, based upon the fact now being established that a diseased alimentary tract is the pathway by which the infection enters the circulation. Many members of one family or community are affected not by direct contagion or heredity, but because of the fact that they usually live under identical hygienic and dietetic conditions favoring the development of rheumatism. The treatment should be prompt and vigorous even though the symptoms be slight, special attention being given to the hygiene and diet. Meat, condiments, too ripe and too green fruits, alcoholic and cold drinks and dishes are to be modified or prohibited. A process of "drainage" or elimination from the bowel, kidneys, and skin is to be instituted before a resort to the salicylates. Salol following magnesium sulphate, is productive of excellent results in patients with catarrh of the bowel.

The Journal of the American Medical Association, March 11, 1905.

Gonorrhea as a Cause of Death.—Joseph Taber Johnson reviews the opinions of authorities as to the effects of gonorrhea in producing female sterility and disease, and states his belief that if the mortality from this cause could be ascertained it would be found to equal that from either typhoid fever, pneumonia or tuberculosis, and that possibly it might be found to exceed the mortality from all three diseases. He thinks that gonorrhea is the cause of at least 30 per cent. of the deaths among prostitutes, and that through its later effects on the generative organs it may be the cause of death in a very large number of virtuous married women.

Myxedema and Diabetes Mellitus.—A. A. Strasser reports the case of a child, 8 years old, in whom the characteristic symptoms of myxedema appeared after weaning. The thyroid treatment was instituted with marked improvement in the symptoms, but diabetes intervened and it was discontinued, not because it was considered responsible for the intervening condition, but to eliminate it as a possible factor. The case was very carefully studied as to its metabolism; the child improved greatly in its mental symptoms as the diabetes progressed, but finally died in coma and convulsions. The author discusses the case with special reference to the effect of the diabetes on the myxedema, and considers the case as absolutely unique. Diabetes mellitus itself is not so rare in children as was formerly thought, but its occurrence in myxedema with the apparent marked effect on the latter condition here observed, has not been reported heretofore. In a supplementary note he refers to two somewhat similar cases reported by Dr. Alfred Gordon in *American Medicine*, February 6, 1904, but he does not agree with the optimistic Gordon's views as to the prognosis in such cases.

Aseptic Operating.—H. T. Byford objects to rubber gloves and impervious covering of the hands on the ground that they produce sweating, and that a scratch or puncture would liberate the accumulation of germ-laden perspiration. He advises soaking the hands thoroughly to soften the cuticle and to loosen the dirt between the epithelial scales, and for this purpose he prefers water drawn in a basin and frequently changed to running water. After soaking the hands and scrubbing them with green soap he advises a scrubbing with diluted acetic, citric, or oxalic acid. This in turn is followed by soaking in 90 per cent. alcohol and then in a 1-1,000 solution of bichloride of mercury. In protracted operations, he advises dipping the hands in the mercuric solution every 10 or 15 minutes to insure asepsis. He does not believe in mixing the solutions of alcohol, green soap, etc., but prefers to keep them separate, and he objects also to sterilized sleeves. Of equal importance is the sterilization of the field of operation. It is easy to sterilize the abdomen, but it is more difficult in case of the groin or genitalia. The shaving should be carefully done to avoid abrasions and the parts scrubbed, not only with soap, but with alcohol and mercuric chloride, and minor operations should receive the same attention as the major. The best after-dressing is sterilized gauze shreds over the sutures and a thick layer of sterilized gauze over these. Inguinal wounds should be washed off after six days and then covered with dry sterile gauze, to be removed daily or otherwise as occasion requires. Dry dressings over peritoneal sutures should be changed every four hours or oftener if they become saturated.

Obstruction of Retinal Arteries.—Allen Greenwood considers at length the three principal causes of obstruction of the retinal arteries, viz., arterial diease, embolism, and spasm. He thinks that primary thrombosis is rare, though thrombosis is frequently a complication of the above conditions. The most important arterial disease is arteriosclerosis, and he points out the earliest danger signals of this condition. They are a slight increase of arterial reflex, slight irregularities in the size of the arteries, slight congestion of the disc, and feathery outline. Where the artery crosses above a vein the latter may be compressed. A little feathery exudate is often seen beside the arteries which should not be mistaken for the opaque nerve fibers often observed. With thickening of the central artery venous pulsation may sometimes be observed ophthalmoscopically; one or all of these conditions may be present. In more advanced cases the light reflex is increased, the arteries become beaded, retinal lesions appear and, finally, we have the full picture of albuminuric retinitis. The early stages of arterial degeneration require the careful inspection of the upright image for their detection. Spasm, the author believes, most frequently occurs in the early stages of arteriosclerosis, and should be looked on as a warning of future obliterating enderarteritis. The treatment of arteriosclerosis is mainly a well regulated life and avoidance of nerve strain and excesses and keeping elimination and digestion unimpaired. Greenwood has been in the habit of advising long-continued use of small doses of iodide of potash. The treatment of embolism is rarely prompt enough to save the function of the retina, but Greenwood advises the early use of vasodilator drugs and deep massage to carry the embolus, if possible, into the smaller branches and to reduce the field defect. For spasm the treatment for arteriosclerosis should be carefully followed. Nitrite of amyl might be used to cut short an attack.

Berliner klinische Wochenschrift, February 20, 1905.

The Clinical Use of Antistreptococcus Serum.—Meyer says great care is necessary for the proper standardization of streptococcus sera that are to be used clinically, and that their strength should always be tested by some authority, who should use for the purpose a streptococcus culture obtained unchanged from human infection and different from the one used by the producer of the serum. The main value of such sera is a prophylactics, and to get proper results its use must not be deferred until it is a last resort. Much judgment is needed to determine the cases in which it is likely to be beneficial, for in some conditions when important organs are seriously invaded, it may prove the reverse of helpful. For example, in malignant endocarditis and in acute rheumatism the injection of antistreptococcus serum is not to be advised.

Dialyzed Diphtheria Poison.—Römer calls attention to van Calcar's experiments on the products obtained by the dialyzation of diphtheria toxin and describes experiments

undertaken by him to test the accuracy of van Calcar's conclusions. The latter author found that on subjecting diphtheria poison in a dialyzer to atmospheric pressure, so that the membrane was put more or less on the stretch, and its pores slightly opened, dialysis took place, and some of the poison passed from within into the outer fluid. After repeated renewal of the external fluid, van Calcar claimed that injection of the residual inner fluid into a guinea pig no longer gave rise to the usual acute diphtheria death, that is toxin action, but only typical toxin action shown by the occurrence of diphtheretic paralysis is the test animals. He thereupon drew the conclusions that he had succeeded by pressure dialysis in separating the toxin from the toxon, and that the toxon molecule is larger than the toxin molecule. Only when the membrane was stretched to the uttermost did any diffusion of the toxon take place. Römer repeated all the experiments and comes to the opinion that it is not possible to separate toxin and toxon in this way, and that dialysis under pressure does not in any way give rise to qualitative changes in the diphtheria toxin.

Münchener medizinische Wochenschrift, February 21, 1905.

Raw or Boiled Milk?—Brüning says that a movement has been started having many prominent advocates which has for its object such regulation of the milk supplies as to render it feasible to feed infants on unboiled cow's milk. The accedents to this view allege that children brought up on raw milk thrive better than is the case when boiled milk is used. The author undertook feeding experiments on animals in order to throw some light on the comparative effects produced by feeding young mammals on raw and boiled milk of a different species. The observation described refers to a litter of four puppies of which two received the natural nourishment, one was given only boiled cow's milk and the other only raw cow's milk. At the age of two months and a half the first two dogs were in splendid condition in every way, the third was considerably smaller, had a more prominent abdomen and a rougher coat, while the fourth dog that had been fed on raw milk was far behind in development, was weak, had nephritis, open fontanelles, a poor coat, etc., and in fact presented a condition simulating rachitis. None of the animals gave a positive tuberculin reaction. While the author does not pretend to draw conclusions from this test, he says that at least we should not be over hasty in advocating the general use of raw milk.

The Treatment of Varicose Ulcers.—Vörner employs two elastic bandages in preference to all other forms of dressing for this condition. The first bandage is applied from the toes upward in accordance with the situation of the lesion, and the second is then applied in the same manner over it, and is fastened either with pins or adhesive. By careful application the degree of pressure can be accurately gauged, and owing to the double layers the dressing is exceedingly stable and does not slip down as ordinary bandages do. In dealing with unintelligent patients it is often advisable to use a permanent dressing, and for this purpose the author employs a fixative composed of tragacanth one-half per cent., gelatine ten per cent., glycerine five per cent., boric acid and sodium borate, of each five per cent. After the first bandage is in position it is saturated with the fixative and the second is applied over it. The solution dries quickly and is very firm. To remove the dressing it is only necessary to immerse the limb for a short time in a pail of water. The method is very effective, and is cheaper than any other of the permament dressings recommended.

The Treatment of Acute and Chronic Gastritis.—Weitlaner is a warm advocate of castor oil in stomach troubles, and says that in cases of acute gastritis his plan is to give a hypodermic of morphine, to forbid everything by mouth, even ice, and in four to five hours to give from twenty to thirty grams of castor oil. Another remedy of great value in chronic gastritis or in the later stages of the acute condition is artificial Carlsbad salt. This is best administered in one gram doses in warm water on rising. Hydrochloric acid is efficient in cases in which the alkali is unsatisfactory, but should be combined with tannic acid. One-half hour after lunch and dinner the patient is to dissolve a 0.1 gr. powder of the tannin in a small glass of warm water, add seven drops of dilute hydrochloric acid and drink the mixture slowly.

Deutsche medizinische Wochenschrift, February 9, 1905.

The Differentiation of the Blood of Biologically Related Animals.—Hamburger was called upon in a criminal case to determine whether certain blood spots were or were not composed of goat's blood. Inasmuch as rabbit serum adapted to goat's blood also gives a precipitin reaction with the serum of related animals such as the sheep and beef, the ordinary precipitin test could not be relied on. The procedure employed consisted in adapting three rabbits, one to goat serum, one to sheep serum and one to beef serum. These sera were then adjusted by dilution or further injections until their value was about equal, and three tests of each were made, one with goat serum, one with sheep serum, and one with beef serum. In each case the reaction was most pronounced in the tube containing serum adapted for the animal from which the authentic serum was added. The salt solution extract obtained from the suspected spot, was then added to the three sera and as the reaction was much more intense with serum adapted to goat serum than with the others, it was evident that the stain contained goat serum. This method may also be employed in order to differentiate the identity of suspected meats.

The Use of Specific Sera in Testing the Identity of Mummy Material.—Uhlenhuth says that his original tests on mummy extract were negative, but that Hansemann and Meyer have published positive results in observations made on two specimens. The author has since then made a study of material obtained from twenty-seven different mummies from two to three thousand years old, but was unable to get a positive precipitin reaction in any case. In some instances the salt solution extract had a strongly acid reaction, which, unless the fluid were neutralized would lead to erroneous conclusions, as acid fluids tend to precipitate the test sera under any conditions. Tests on mummified material of more recent date, one of the specimens being sixty-six years old and the others less ancient, gave positive reactions, however, and the author is undertaking further observations in order to determine, if possible, the length of time that must elapse before the precipitable bodies are rendered inert.

The Treatment of Coryza.—Henle relates the happy effects experienced when in a severe attack of coryza in his own person, he tried Bier's congestion treatment applied to the neck by means of the pressure tube of his own invention. The pressure was run up to 25 mm. of mercury without producing any discomfort and with very prompt relief to the subjective nasal symptoms, and a repetition of the treatment a few hours later caused all symptoms to disappear completely. A trial of the plan on five other patients gave equally satisfactory results in all save one, in which only a single application was made, but without any effect. This patient was the subject of chronic rhinitis. The plan is absolutely harmless in patients with normal arteries, though the pressure should never be raised above 25 mm. of mercury; and the author counsels its trial in all acute inflammatory conditions about the nose and throat.

French and Italian Journals.

Relations Between Arterial Pressure and Absorbed Doses of Chloroform.—According to Tissot, it has been demonstrated that chloroform causes death by its toxic action on the heart or cardiac nervous centers. It is easy to study this toxic action on the heart by substituting for the direct examination of cardiac contraction that of arterial pressure which faithfully reproduces the modifications. The object of these observations has been to study the relations that exist between the doses of chloroform absorbed and the modifications of arterial pressure which they determine. Besides this, the effect of the same doses on the respiratory movements has been noted. As a result of these observations, the following conclusions are presented: The depressing action of chloroform on the heart or on the arterial pressure increases regularly with the dose of chloroform absorbed. The doses of chloroform which in the dog do not lower the arterial pressure below 10 cm. of mercury, do not cause any accidents. The doses of chloroform which produce only respiratory arrest in the dog are those which lower the pressure between 10 cm. and 6 cm. of mercury. The doses of chloroform which cause cardiac syncope are those which lower the arterial pressure to the neighborhood of 5 cm. of mercury or below. Accidents incident to the use of chloroform in the dog can be positively avoided, even if the drug is given without precautions, if care is given to administer such a quantity that the arterial pressure will continue more than 10 cm. of mercury. If a sufficiently delicate instrument is applied to the artery, it will, like the manometer in the case of the dog, indicate the degree of cardiac intoxication. When the dose of chloroform is large enough to determine accidents, arterial pressure is influenced well before respiratory arrest or even before an alarming modification of the respiratory mechanism is produced. Besides the tardiness of respiratory indications, they are often difficult to appreciate.—*Le Bulletin Médical,* February 22, 1905.

Experimental Diagnosis of Smallpox and Chickenpox.—P. Salmon, Vincent, declares that inoculation of the pus from the pustules, practiced by simple application to the cornea of the rabbit, affords the means for making a rapid and positive diagnosis between the two diseases. Chicken-

pox yields only a negative result, while smallpox pus gives rise to transparent visicles, easy of recognition by the aid of a magnifying glass or by oblique illumination. L. Martin has noted in regard to monkeys, that attempts at inoculation of chickenpox always give negative results, an observation which stands in line with the work just mentioned, and which, like it, establishes a new distinction between smallpox and chickenpox.—*La Tribune Médicale,* February 18, 1905.

Prognostic Value of Ehrlich's Diazo Reaction in Pulmonary Tuberculosis.—Holingren believes that although the value of the diazo reaction from the standpoint of diagnosis may seem to have been exaggerated, in respect to pulmonary tuberculosis, it offers an important element from the prognostic point of view. This reaction fails in more than two-thirds of the cases of advanced tuberculosis; it is exceptional in the first stage of the illness, and shows itself with some frequency only in the third period or at the end of the second. But when it does appear, it is an excellent indication of the future duration of the disease. This observer has divided the results of these reactions into four classes: Very clear, clear, doubtful or nil. Of the patients belonging to the first class, 60 per cent. succumbed within two months, and 51 per cent. in six months; two only out of the twenty-three in the series, survived after eighteen months. Of these two patients, one has chronic pleurisy, and the other had chronic rheumatism, and they consequently offered a soil less favorable for bacillary evolution. In the second class, reaction distinct, the mortality at the end of two months was 30 per cent.; 50 per cent. at the end of six months, and 76 per cent. at the end of eighteen months. For those in the third class, reaction doubtful, the mortality was lower—10 per cent., 16 per cent., and 36 per cent., respectively. In the group of advanced cases in which the reaction was not present, there was no death in the first two months; 9 per cent. only after six months, and 32 per cent. after eighteen months. In patients suffering from tuberculous pleurisy only, the reaction failed; and all of the patients in the last class who could be kept under observation until death, finally showed a positive reaction. Holingren believes that the duration of the survival of tuberculous patients is in inverse ratio to the intensity of the diazo reaction. When the reaction is very definite, the patient will probably rapidly succumb—within two months—and has little chance of living more than six months. With a doubtful reaction one may hope for eighteen months. If it is negative, one can count on exceeding this.—*Revue Française de Médecine et de Chirurgie,* February 6, 1905.

Experimental Degenerative Gastritis.—Hayem has recently demonstrated the nature of lesions of degenerative gastritis which occur in the course of infectious maladies. He has been able to reproduce lesions absolutely similar, by the injection into the blood vessels of a dog, of the toxin of diphtheria in repeated small doses. It appears from these experiments that it is the toxins which, carried by the blood current, produce the injury to the glandular elements. On the other hand, in certain patients presenting the asetic type in whom there did not exist former gastric troubles, which would explain the present condition, it is probable that a former infection was the cause of the degenerative gastric lesions, explaining the modifications of the stomachal secretion.—*La Presse Médicale,* February 22, 1905.

The Pathogenesis of Dissociation of Sensibility of Central Origin.—Ugo Benenati has collected 31 cases, divisible into two categories, (a) syringomyelia with thermic sensibility present, in which the gray commissure was intact; (b) cases with abolition of thermic sensibility, in which the gray commissure was injured. From the study of these cases he concludes the great importance of the posterior gray commissure to be demonstrated in the transmission of thermic sensibility. Clinical facts are in accord with the author's experimental results in pointing out that the posterior gray commissure of the medulla is the organ of transmission of thermic impressions. Grasset has shown that disturbances of the sweat and vasomotor functions, thermoanesthesia and analgesia are the result of lesions of the central gray substance of the medulla, and the bulbar structures.—*La Riforma Medica,* February 4, 1905.

Sugar in the Treatment of Pulmonary Phthisis.—Massalongo and Daneo have given much attention to those methods of treating phthisis connected with supra-alimentation, especially by the use of ordinary sugar, and have made a series of experiments, of which they give us the results. Sugar is not only a heat-producing food but also one that produces energy, and is especially useful to prevent emaciation. It should be given in phthisis in large amounts outside of the regular meals, 100 to 500 grammes per day. Weight is gained rapidly, in a few months 8-15 kilogrammes increases being shown. In some instances the gain in weight each day was greater than the amount of sugar ingested. While the sugar was being administered there was no glycosuria, though there was a decrease in the amount of oxidation compounds. The most encouraging results were obtained in cases without fever, or with only a slight rise of temperature. The sugar was generally well taken and assimilated by the patients; in some cases there was intestinal fermentation. The sugar could be masked by the use of milk or black coffee, or bitter tinctures. Even in some febrile cases the sugar was well tolerated, and in those cases that could not take cod liver oil.—*Annali di Elettricita Medica e Terapia Fisica,* January, 1905.

Nephritis and Breast Feeding.—Luigi Concetti discusses the advisability of allowing an infant to nurse while its mother suffers from nephritis. Roger, in the hospital for infective diseases in Paris, allowed 100 infants to continue nursing during the progress of the illness of women suffering from measles, scarlatina, diphtheria, and erysipelas, while using all possible precautions against direct contagion. He found that the children in general did well, and that the mortality was less than when the children were artificially fed. The author cites the case of a four months' old child, who did well while nursing his mother through five weeks of acute nephritis, but when put on artificial food developed an acute intestinal trouble so severe that he was returned to his mother in two weeks. On breast milk he improved rapidly, gained in weight and soon was well. The mother, too, seemed to improve under the change. As we do not know what poison causes the symptoms of acute kidney disease, and as antitoxins and immunizing substances are known to pass into the milk, a state of immunity may be developed in the infant through the mother's milk. The author concludes that a child should continue nursing during nephritis of the mother, while carefully observed, and a daily urinary examination made, to guard against the development of an acute nephritis in the child.—*Rivista di Clinica Pediatrica,* January, 1905.

Puerperal Nephritis or Nephritis in the Puerperium?—Silvestri Torindo believes that we cannot admit that there is a toxemia dependent on pregnancy. The clinical and experimental facts are favorable to the conception that eclampsia is a syndrome resulting from varying factors; pregnancy has no other office than to prepare the ground, producing in the cerebral organism of the pregnant woman peculiar conditions, which may be physiologically reproduced in the brain of the infant. Pregnancy, inasmuch as it determines lessened resistance of the nervous system and overloading of emunctories, with insufficient action of the glands of the mother that produce antitoxic actions, is a powerful predisposing factor in the etiology of nephritis. Therefore we should rather speak of nephritis occurring during the puerperium than of puerperal nephritis.—*La Riforma Medica,* February 15, 1905.

Vascular Pathology of Progressive Paralysis in a Baby.—Campana reports the histological examination of the capillaries in the brain of a syphilitic child, who died as the result of accident while in the early stages of syphilis, showing the presence of infiltration about the arteries. This examination accords with the examination of other cases made by him, and with those of incipient tabes of like origin. The author believes that we should not be content with the examination of the early stages of the disease alone, but the results should be controlled by new researches, which, he predicts, will accord with his results, or will show the reason of the different results obtained by different authors.—*La Riforma Medica,* February 18, 1905.

Orthostatic Albuminuria.—Giuseppe Evoli characterizes orthostatic albuminuria as a transitory condition, not the expression of a true morbid state, but functional, and occurring without loss of health. It occurs in individuals of nervous heredity and general bad development, in young subjects possessed of an unstable nervous system. The condition seems to be somewhat rare. It is cured by rest in bed and general nutrition. Its chief characteristic is that it occurs only when the patient is occupied so as to be on his feet most of the time, and disappears with rest in bed, to reappear when the erect position is again maintained. The amount of albumin is from one-half to one gramme per liter, and there are no casts, and no indication of gastric failure. It is rather a dynamic than an anatomical condition. Our author regards it as a state of insufficiency, determined principally by atonia of the circulatory apparatus, which is exaggerated by the erect posture to such an extent as to produce dystrophy of the glomerular epithelium and allow a certain amount of albumin to pass into the circulation.—*Giornale Internazionale delle Scienze Mediche,* February 15, 1905.

Book Reviews.

A Dictionary of New Medical Terms, Including Upwards of 38,000 Words and Many Useful Tables, Being a Supplement to "An Illustrated Dictionary of Medicine, Biology, and Allied Sciences." By George M. Gould, A.M., M.D., Author of "The Students' Medical Dictionary," "30,000 Medical Words Pronounced and Defined," "The Meaning and Method of Life," "Borderland Studies," Editor of *American Medicine*, etc. Based upon Recent Scientific Literature. Philadelphia: P. Blakiston's Son & Co., 1905.

This work, as its title declares, is supplementary to Dr. Gould's monumental dictionary of medical terms, and is intended to define all the words which have been coined in the decade since the publication of the first edition of the original work. Most of the titles are therefore contained in the later editions of the dictionary, yet there are many, so rapid is the progress of medical science, that are not to be found in even the latest edition of Gould's lexicon. The reviewer of a dictionary has several tasks before him. He must determine whether the work he is reviewing is reasonably complete—absolutely complete it can never be, for even in the interval between the final correction of the proof sheets and the publication of the book not a few terms will appear in the literature which a captious critic might cite as evidence of the shortcomings of the work. He must take note of the definitions—whether they are correct, explanatory, and clear. And finally he has to note the orthography, whether it is in accord with accepted standards and whether it is consistent. With the etymology he has little concern, for unless the author is an ignoramus or possessed of unusually fantastic imagination his derivations can hardly fail to be correct. Approaching the book with these aims in view, we must admit its completeness. Some of the most recent coinages are, of course, absent, but to make up for these there are many words—hundreds, we were going to say—which are more positive words, never, please heaven, to be found again in medical or any other literature. The definitions are excellent—clear, concise, and satisfying. But the spelling is confusing and inconsistent. English orthography is bad at its best, but when innovators take a hand at its simplification they invariably make a mess of it. Language is a stubborn thing and will follow its own sweet way regardless of purists and sticklers for consistency who never are consistent. Dr. Gould is an advocate of single vowels in place of diphthongs, yet he gives us "leukæthiopia" (misplaced after "leukemia"). He favors the use of *k* in place of *c* in such words as "leukocyte," yet we find "leucotoxic" and "leucotoxin" (misplaced after "leukotaxis" and a number of words of similar derivation spelled with a *k*). "Katalysation" has an initial *k*, but "catalysis" is written with initial *c*. We wish the author had adhered throughout to the use of *c* to denote the Greek *k* before a hard vowel, in accordance with the usage of the best English writers, but if he must use the ugly *k* he ought to stick to it and not confuse his disciples—of whom he has unfortunately a considerable number among the medical writers in this country—by jumping about from *c* to *k* and *k* to *c* with apparently no rule but the whim of the moment.

But, having delivered himself of this expression of dissatisfaction with the author's orthographical vagaries, the reviewer turns from criticism to commendation. This work is one that no medical reader can well dispense with; it is a supplement not only to Gould's dictionary but to all others—of which the name is legion. It contains many titles not to be found in even the latest of the medical dictionaries, and will be found useful to the possessor of any of these. It is, of course, not a complete medical dictionary; it is only—and this is all that it claims to be—a supplement to other dictionaries, but as such it is worthy of all praise. The user of it can rely upon the definitions, and he will find few new words not defined; he had better not follow slavishly the orthography, but he is not likely to do so if he has been well grounded in the rules of English spelling, and he can overlook these faults in the presence of so much that is helpful.

Eye, Ear, Nose, and Throat Nursing. By A. Edward Davis, A.M., M.D., Professor of Diseases of the Eye in the New York Post-Graduate Medical School and Hospital, and Beaman Douglass, M.D., Professor of Diseases of the Nose and Throat in the New York Post-Graduate Medical School and Hospital. With 32 Illustrations. Philadelphia: F. A. Davis Company, 1905.

While the manual of Yearsley, published in England some years ago, left little to be desired, it seems not to have become well-known in this country, and we welcome this new book by American authors. Dr. Davis has written the chapters on the eye (pp. 1-168), and Dr. Douglass those on the ear (pp. 170-227), nose and throat (pp. 229-307). Each section opens with a brief description of the anatomy and physiology of the parts, and is followed by an enumeration of the common diseases and full directions for their cure by the nurse. Special stress is laid upon the necessity of full antiseptic precautions in work on these local areas, and nothing of importance seems to have been overlooked. We unhesitatingly commend this manual for the use of nurses.

Life Insurance Examinations. A Manual for the Medical Examiner and for All Interested in Life Insurance. By Brandreth Symonds, A.M., M.D., Medical Director of the Mutual Life Insurance Co. of New York; Lecturer on Life Insurance Examinations at the University and Bellevue Hospital Medical College. New York and London: G. P. Putnam's Sons, 1905.

Although this little volume is written with the special purpose of assisting medical examiners for life insurance companies in performing their often difficult duties, it is of a nature to be interesting and instructive to all practitioners. The question of prognosis is one that most vitally concerns both the patient and his friends, and good judgment or the lack of it in this respect may make or mar a professional reputation. The vital statistics which render life insurances commercially possible are equally valuable in estimating the patient's prospects, and the many hints on the tactful conduct of physical examinations, etc., should render the book helpful to young practitioners. The subject matter comprises a good deal of information regarding the general nature of life insurance companies, the different features of the examinations of applicants, relations with agents, frauds and fraudulent practices, etc., and in an appendix the examination of urine and the subject of heart murmurs are discussed.

The Surgical Diseases of the Genito-Urinary Tract, Venereal and Sexual Diseases. A Text-Book for Students and Practitioners. By G. Frank Lydston, M.D., Professor of the Surgical Diseases of the Genito-Urinary Organs and Syphilology in the Medical Department of the State University of Illinois (The Chicago College of Physicians and Surgeons); Professor of Criminal Anthropology in the Chicago-Kent College of Law, etc. Revised Edition. Illustrated with 233 Engravings and 7 Colored Plates. Philadelphia: F. A. Davis Company, 1904.

The second edition of this thoroughly satisfactory book has required but little revision to keep it in its place among the foremost of our text-books on this subject. Radical changes in second editions often mean ill-considered or hasty work in the first impression, but every chapter in this book bears witness to the thoughtful care with which it was prepared in the beginning, and the present text should maintain its authoritative position for many years. Somewhat more space than before is given to the mention of the newer silver derivatives, which the author considers the best remedies at our command for the systematic local treatment of gonorrhea. The illustrations have also been improved in general tone by judicious substitutions and additions, though it must be admitted that the colored plates are not above the average in execution. The author's fluent style and wealth of experience make the volume not only instructive but also very agreeable, and it is a pleasure to commend it to all classes of medical readers.

Grundsätze für den Bau von Krankenhäusern. Von Generalarzt Dr. Thel, Korpsarzt des XI. Armeekorps. Mit 11 Tafeln und 66 Figuren im Text. Berlin: August Hirschwald, 1905.

The subject of hospital construction is too broad and far-reaching a one to permit of adequate consideration within the compass of a volume of 125 pages, of which a large proportion are given up to the sixty-six figures introduced. The little book is excellent as far as it goes, and contains many interesting plans of German and other hospitals, but it is hardly extensive enough to be of much value to anyone really in need of a working knowledge on this topic.

Uncooked Foods and How to Use Them. A Treatise on How to Get the Highest Form of Animal Energy from Food. With Recipes for Preparation of Healthful Combinations and Menus. By Mr. and Mrs. Eugene Christian. New York: Health-Culture Co., 1904.

The authors of this book think that cooking destroys some vital element of food, and that man would be better off if he never subjected anything to go into the stomach to a temperature above 145° F. A housewife might find some good recipes for salads and other raw foods in this book, but we see no other reason for its publication. The scientific accuracy of the authors' statements is well illustrated by the following quotation (p. 105): "Bread rises when infected with the yeast germ, because millions of these little worms have been born and have died, and from their dead and decaying bodies there arises a gas, just as it does from the dead body of a hog or any other animal."

Society Reports.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 2, 1904.

The President, Dr. Charles L. Dana, in the Chair.

The Hypodermic Use of Adrenalin Chloride in Asthmatic Attacks.—Dr. D. M. Kaplan read a paper on this subject, in which he offered the following conclusions: 1. That this remedy had a distinct place in the therapeusis of asthmatic seizures. 2. That the effect produced by it apparently substantiated, in certain cases, the vasomotor origin of the seizures. 3. In the writer's experience, the contraindications to the drug were generally overstated. 4. Even large doses, freely used, did not give rise to glycosuria, although relieving the paroxysms with greater promptness and certainty than most of the other drugs at our command. 5. The hypodermic use of adrenalin was in no sense curative of the disease, as such.

Dr. W. Gilman Thompson said he had used adrenalin to some extent, and had been rather disappointed in the effect of its hypodermic use in asthma, which he thought was perhaps due to the fact that he had not employed it in sufficiently large doses. The results of animal experimentation with the drug, as compared with the clinical results in man, were very contradictory. Several writers had recently questioned the ability of the organism to absorb much of the drug when given hypodermically, its local effect on the neighboring vessels being such as to constrict them. The speaker said he was not convinced that it was very active in controlling any form of internal hemorrhage. It was a rather curious fact that for years vasodilators, such as amyl nitrite, had been recommended in the treatment of asthma, and that now a remedy was brought forward for the same condition which produced a diametrically opposite effect.

Dr. Andrew H. Smith said that some years ago he made quite a series of observations with the use of oxygen gas in asthma, and he was soon struck by the fact that while certain patients were immediately relieved by the inhalation of the gas, others remained entirely unaffected by it. He attributed this to the fact that we had to deal with different varieties of asthma. In some instances the asthmatic attacks were due to a tumefaction of the bronchial mucous membrane; in others to a constriction of the muscular tubes or of the branches of the pulmonary artery from reflex or vasomotor causes. With constriction of the branches of the pulmonary artery, the supply of blood would be interfered with, and this might produce all the clinical phenomena of asthma.

Dr. John B. Huber referred to a paper by Sajous on the subject of the ductless glands, in which the idea was advanced that the red blood corpuscles, which contained the hemoglobin and perhaps oxygen, did not reach all the tissues of the body, and that the adrenal glands secreted a ferment which permeated these minute tissues and supplied them with oxygen. The good effects of adrenalin might be explained on this theory.

Dr. S. Wachsman, who had witnessed many of the experiments made at the Montefiore Home by Dr. Kaplan, said that the drug had a strikingly beneficial effect upon the asthmatic attacks as compared with the older remedies, such as hyoscine, atropine, and morphine.

The President called attention to the experiments of Dr. Meltzer, who had produced edema of the lungs in rabbits by injections of adrenalin. The speaker also mentioned the fact that the use of the drug was sometimes followed by certain nervous symptoms.

Dr. Kaplan, in closing, said that in long-standing cases of asthma, the usual dose of adrenalin chloride was not sufficient. In such cases he had seen satisfactory results follow a dose of twenty-five or thirty minims. The asthmatic attack was usually cut short in less than five minutes. The cases that were mainly influenced by the remedy were those of bronchial asthma occurring in the course of emphysema. The speaker said he had used the drug in pulmonary edema with very satisfactory results.

A Case of Dibothriocephalus Latus Infection, Causing Pernicious Anemia, with Complete Recovery. Dr. W. Gilman Thompson reported the case of a boy of seventeen, a native of Finland, who was employed as a plumber's apprentice. His family history was unimportant, and he had always enjoyed good health until about seven months prior to his admission to Bellevue Hospital, when his increasing pallor first became noticeable. A month later, repeated attacks of epistaxis occurred, on successive days, one of which lasted half a day. He also began to suffer from dyspnea on exertion. A month before admission his legs became edematous, and as his weakness increased, he lost some thirty pounds in weight, and having had about fifty attacks of epistaxis, he applied to the hospital for relief. A month previous to his arrival at the hospital he took a dose of a decoction made from some seeds which had been sent to him from Finland to rid him of a tapeworm of several years' growth. He stated that many of his countrymen were similarly affected. He passed about four feet of the worm, as he thought with the head attached. Upon admission, the boy presented a typical clinical picture of pernicious anemia. He appeared well nourished, but was of a pale, lemon-yellow color. There was moderate edema of the legs, and the cervical glands were enlarged upon the left side. The pulse was quick and compressible; the heart appeared normal in size, but presented an apical systolic bruit, and another at the base, transmitted to the vessels of the neck; the pulmonic second sound was accentuated. The leg reflexes were diminished, but there were no other nerve symptoms. The abdominal viscera appeared normal. The urine was slightly albuminous, with a few hyaline casts and a specific gravity ranging between 1,007 and 1,010. There was moderate dyspnea and a few crepitant râles were heard at the base of the right lung. The patient had repeated epistaxis, but examination of the nasal cavities revealed nothing abnormal. The optic discs were very pale, with small veins and arteries, secondary atrophy and several small hemorrhages in the fundus, but none in the maculæ or periphery. Motion of the eyes and vision was normal, but the patient had had a transient attack of blindness the week before his eyes were first examined. His temperature on admission was 104° F., and remained so for three days, with a pulse of 120. For two weeks after that it ranged between 100° and 101° F., subsequently becoming normal. Soon after admission, the ova of the dibothriocephalus latus were observed in the feces, with a few red blood cells. During a period of eight weeks the patient was given five doses of the oleoresin of aspidium, one drachm in each dose, and on four occasions thereafter he passed several feet of the parasite—in all about thirty-five feet—but no head was discovered. The administration of male fern was preceded by a period of starvation, and followed in twelve hours by castor oil. After three weeks of treatment, the hemorrhages ceased, and the general condition, including the anemia, began to show steady improvement, which was maintained until the patient was discharged after three months, apparently cured and with normal blood. In connection with the history of this case, Dr. Thompson showed a table of six representative blood analyses made during the course of the patient's illness. The features of special interest in the blood examinations were: 1. The complete restitution of the red cells from a count of 608,000 to 5,980,000, and of the hemoglobin from 20 per cent. to 98 per cent. 2. The early high color index (1.6). 3. The absence of eosinophiles in the earliest examinations. 4. The early high percentage of macrocytes. 5. The early presence of normoblasts and megaloblasts. 6. The leucopenia.

Two Cases of Pernicious Anemia Due to the Bothriocephalus Latus.—Dr. Alfred Meyer reported these cases. The first was that of a female domestic, 22 years old, a

native of Finland. She was admitted to Mt. Sinai Hospital on November 6, 1903. She stated that for a year prior to her admission she had suffered from weakness, with increasing pallor. This was marked, and of a yellowish hue. There were loud systolic murmurs at the apex and in the aortic area, with slight edema of the extremities. A blood examination showed red blood cells, 780,000; white blood cells, 5,000; hemoglobin, 15 per cent. There were numerous ecchymoses upon the arms and about the ankles and trochanters, and large retinal hemorrhages, especially in the right eye. The temperature ranged from 100° to 102° F. during the patient's first fortnight in the hospital. On the eighth day after admission ova were for the first time found in the stools, but they were not recognized as those of any known parasite. A few days later, thirty grains of thymol were given in two doses, and four hours later, a tapeworm was passed which proved to be a bothriocephalus latus, measuring almost nine feet in length. Ova were still found in the stools from time to time until nine days after the expulsion of the worm, when they disappeared for a period of three weeks and then were again found for one day only. The improvement of the patient was immediate and truly marvelous. The mucous membranes rapidly improved in color. She gained thirteen pounds in weight, the hemoglobin rose from 15 per cent. to 63 per cent., and the red blood cells from 780,000 to 3,460,000. The second case reported by Dr. Meyer was that of a woman who was still an inmate of Mt. Sinai Hospital, to which she was admitted on December 7, 1904. She was 25 years old, married, and a native of Poland. Her illness began about two months before the birth of her first child, with a swelling of the feet and legs. About the same time her pallor became noticeable and progressively increased. She stated that she saw segments of a worm in her stools about a year before. Upon admission, there was marked pallor of the body and mucous membranes, with an icteric tinge. There was edema of the lids and extremities. A systolic murmur was heard at the apex and in the pulmonic area. Her temperature was 101.2°. A blood count showed 660,000 red blood cells; 5,400 white blood cells, and 10 per cent. of hemoglobin. Dr. E. Gruening, who examined the fundus, reported numerous hemorrhages along the veins; also hemorrhages where there were no veins. An examination of the stools showed a large number of ova of the bothriocephalus latus. Thymol was given in half drachm doses, preceded and followed by castor oil, but the worm was not expelled. The same negative result followed the use of the ethereal extract of filix mas. On December 19 the red blood cells numbered 556,000, a loss of a hundred thousand in eleven days. On January 3, 1905, the red blood cells numbered 468.000, another loss of about ninety thousand. On January 7 some segments of bothriocephalus latus passed, and ova were found for the first and only time since the administration of anthelmintics was begun. Many and varied doses of thymol, filix mas, and pelletierine sulphate were employed, but without expelling the parasite. On January 16 the red blood cells numbered 1,176,000, having nearly trebled in thirteen days; the white blood cells numbered 5,800, and the hemoglobin was 21 per cent. The case was still under observation.

A Case of Double Infection with Uncinaria Duodenalis and Strongyloides Intestinalis.—Dr. William P. Northrup reported this case. The patient was a girl of nine years. Both of her parents were dead; cause unknown. The child was born and had always lived in South America up to six months ago. The past summer she had spent in Tennessee and Alabama. Up to two years ago she had lived under the poorest conditions, in a neighborhood where many died of dysentery and starvation. Her present illness began about eighteen months ago, her chief trouble being continued looseness of the bowels. She had at times from fifteen to twenty movements of the bowels a day, the stools being loose and containing blood and mucus. Since she came to this country, six months ago, her condition had slowly improved. There had been protrusion of the bowel from the anus following each movement. Her general health varied with the severity of the dysentery. When it was most severe she lost flesh and strength, became pale, short of breath, and showed no inclination to play. For the past six months she had been improving. Her bowels moved five or six times a day, her color was better, and she had more strength. The blood examination showed a moderate secondary anemia, with marked increase in the eosinophile leucocytes, suggesting the presence of some intestinal parasite. Examination of the feces showed segmenting ova, which appeared to be those of the uncinaria duodenalis (or ankylostoma duodenale—the hook-worm). Ova of trichocephalus dispar—the whip-worm, were also found. Under treatment the patient had improved, but was still under observation.

Dr. Fred Palmer Solley, who had made the microscopical examinations in the case reported by Dr. Northrup, said that, beside the ova of the uncinaria duodenalis and the trichocephalus dispar, free-swimming embryos were seen a few days later in the freshly passed stools. These embryos were of the so-called rhabditiform type, with a short, bottle-shaped esophagus. So far as their appearance was concerned, they might have been those of either uncinaria duodenalis or strongyloides intestinalis—the Cochin-China diarrhea worm. Further observation showed that the numerous segmenting ova present in the feces of this case were uncinaria ova, while the embryos were held to be strongyloides intestinalis. This opinion was confirmed by Dr. Stiles of Washington, to whom a specimen of the feces was sent. Ciliated infusoria, apparently the trichomonas intestinalis, were also observed from time to time in the stools. These had no especial significance, excepting that they seemed to thrive under catarrhal conditions of the intestine. The trichocephalus dispar, mentioned above, was also of no pathological importance. The association of the uncinaria with strongyloides intestinalis was, however, of great interest. The predominant effect of the combined infection in the case under discussion had been a persistent diarrhea, lasting eighteen months. The anemia in this case had not been pronounced, the red cells ranging from four to five millions, and the hemoglobin from 60 to 65 per cent. Evidently the uncinaria, which were capable of producing grave forms of anemia, were not present in great numbers. Indeed, their ova had now almost disappeared under repeated small doses of thymol, and but one mutilated representative of the adult hook-worm was found in the stools during treatment. The diarrhea was apparently the direct result of the presence of the Cochin-China diarrhea worm, since the number of embryos in the stools was noticed to be in proportion to the severity of the diarrhea. The leucocytes in this case gave the first clue to the condition. The total leucocyte count had ranged from 9,000 to 27,000, and seemed to vary with the severity of the diarrhea and the number of embryos present in the stools. There had been a constant eosinophilia of from 12 per cent. to 39.5 per cent., and it was well known that an increase of eosinophiles was very constantly associated with uncinariasis.

The Limitations of the Value of Nitroglycerin as a Therapeutic Agent.—Dr. H. P. Loomis, read this paper. (See page 411.)

Dr. Egbert Le Fevre said his results with the use of nitroglycerin had been somewhat different from those reported by Dr. Loomis. The effects of the drug varied, according to the type of arterial tension one had to deal with. After progressive fibrotic changes had occurred in the arterial walls, and there were practically no muscular elements left, little could be expected from nitroglycerin in its action upon the general circulatory system. In another type of cases, which had been variously described by different writers, there was a tonic high tension pulse, with more or less evidence of cardiac hypertrophy; in these cases the condition responded very quickly to small doses of nitro-

glycerin, but the beneficial effects of the drug were transient. Dr. Le Fevre said he had seen two cases in which the use of large doses of nitroglycerin had been followed by cerebral hemorrhage. In both of these the head symptoms produced by even ordinary doses of the drug had been very profound. In one of the cases, in which the dose was increased from 1-50 to 1-25 of a grain, the patient developed the symptoms of a cerebral hemorrhage, and that lesion was found at autopsy. The second case was practically identical.

Dr. W. Gilman Thompson said he was inclined to agree with Dr. Loomis that nitroglycerin was often an unreliable remedy, and that if given at all, it should be given fearlessly and in good-sized doses. The drug was used too much as a matter of routine, just as strychnine was for its opposite effect.

Dr. Andrew H. Smith thought that nitroglycerin or nitrite of amyl was of distinct value in certain cases of cyanosis, especially connected with pneumonia.

Dr. Henry W. Berg referred to the recent experiments on dogs made by Dr. Crile of Cleveland in connection with the treatment of surgical shock. Crile found that the various stimulants that we were in the habit of laying so much stress upon—including alcohol, adrenalin, ether, and nitroglycerin—produced but a very slight increase in the blood pressure, and that soon after an injection of nitroglycerin the blood pressure was very much diminished. Dr. Berg said that in cases of failing heart occurring in the course of bronchopneumonia or diphtheria, he thought that nitroglycerin was the only drug of any real value. He also placed the greatest reliance upon it in acute pulmonary edema complicating aortic regurgitation. The speaker thought the action of nitroglycerin was a vasomotor one, dilating the terminal arterioles.

Regular Meeting, Held February 16, 1905.

Dr. Charles L. Dana in the Chair.

A Contribution to the Pathology of Sciatica.—Dr. J. Ramsey Hunt presented this communication, and said that the study of the underlying pathological changes in sciatica was rarely taken up because of the fact that so few died during an attack, the disease not being a menace to life. He had been able to collect but eleven cases in which the condition of the nerve was noted post mortem, three of these receiving but an histological study. During the past fifteen years there had been no records of post-mortem examinations of those dying with sciatica. Sciatica he divided into two groups, first, the neurotic, with slowly developing symptoms, and, secondly, the neuritic, with inflammation of the sheaths and inflammation of the nerve fibers, and it was in this latter group that most of the cases of sciatica belonged. It was interesting to note that, in many cases, the local findings showed fine powdery deposits of urate of soda, similar deposits being found in the joints, and the nerve at some later period becoming saturated with urate of soda. The speaker then summarized the facts presented at autopsy in the eleven cases collected from the literature. He then gave a history of a patient, fifty-nine years old, who had an attack of sciatica on the left side in November, 1902. In six weeks the symptoms disappeared. In February, 1903, sciatic pains became very severe in the left leg, and the patient then applied for treatment. There were the usual tender points, but there were no demonstrable objective disturbances of sensibility. The muscles of the left thigh, the buttocks and leg showed fibrillary twitchings. There were signs of an arteriosclerosis. His symptoms became so acute that he was sent to Bellevue Hospital. In about three weeks the symptoms abated, and the patient was allowed to return to his home again. In standing or walking he favored the left leg, and there were twitchings in the muscles of the left side. The Achilles jerk became less in intensity. The left thigh and leg underwent a slight passive atrophy. The patient developed a croupous pneumonia and died on March 23, 1903. A complete autopsy was not allowed, but permission was given for examination of the affected nerve, the sciatic, as far down as the popliteal. In going downwards the trunk of the nerve was of greater volume than normal, due to the deposits of gelatinous material, some of this material being deposited in the popliteal space as well. The bifurcation of the internal popliteal nerve presented a normal appearance. The increase in the size of the nerve was not due to edema, but to firm, homogeneous, translucent deposits in the perineurium. In the examination of the microscopical sections there was no infiltration of round cells found, nor any signs of an acute inflammation. No fibrin could be demonstrated. The nerve fibers were free from deposits. The connective tissue was thickened along the course of the arteries of the sheath, which were markedly sclerosed and thickened. There was a small extravasation of blood found in the sheath. The examination of adjacent muscles gave negative results. In the case reported by Dr. Hunt there was no question as to the correctness of the diagnosis of sciatica. He did not care to express any opinion regarding the pathological nature of the cases reported, or his own, but they did seem to relate closely to gouty states.

Dr. B. Sachs said that the findings in Dr. Hunt's case might have been exceptional ones; all were not at all agreed that these deposits along the sheath of the nerve were gouty. The case strongly suggested the possibility of syphilis; all knew that gelatinous deposits were seen in syphilis of the spinal cord along the greater length of the cord, so that if these were not gouty deposits, the possibility of their being syphilitic should be borne in mind. This would, in his opinion, go a long way towards proving a syphilitic perineuritis.

Dr. James J. Walsh thought it was unfortunate that the term uric acid should have been introduced into the discussion, because it was a term we were trying so hard to get away from. Even though we knew little about the gouty manifestations we did know that they were earned rather than hereditary. Some people had too much lead and others too much alcohol in their systems. Certain nerves were most prone to be affected according to their uses; for instance, the tailor might suffer from lumbago, the shoveller from sciatica, the woman with much sweeping from neuritis in the forearm, etc. It should be borne in mind that the particular nerves the patients were in the habit of using were the ones most liable to disturbances.

Dr. Robert T. Morris said that fifteen years ago he operated a number of times upon the sciatic nerve, stretching it, for sciatica, but during the past two years he had not been called upon to stretch even once. He asked the reason for this. Even admitting that many of the cases were due to a toxemia, entirely separated from cases due to a direct mechanical irritation, he asked why more cases were not seen to-day. A rational explanation for the presence of the gelatinous fluid would be as follows: First, a neuritis; then a plastic exudation; then an adhesion between the nerve sheath and the nerve; later an attack of sciatica would be excited by the irritation caused by these adhesions. It would be remembered that these adhesions were well defined between the nerve and its sheath. Subjecting the nerve to fifteen or twenty pounds weight would pull the adhesions out, and in some cases the relief would be permanent, then again others would be marked by recurrences. To-day in commencing attacks of sciatica it would be well to remove the prostate, fasten up a uterus, or do some other operation which would remove any direct mechanical pressure upon the sciatic nerve.

Dr. J. Ramsey Hunt said that there was no possibility of syphilis in the case he reported.

The Treatment of Acne.—Dr. George Thomas Jackson read this paper. (See page 408.)

Phases of Grip, 1904-1905.—Dr. James J. Walsh said that it was now about fifteen years since the pandemic of influenza began in Bokhara in Central Asia and spread westward throughout the civilized world. The disease

was apparently communicated from person to person. None of the civilized countries were spared, and the death rate was as high as in most of the historic epidemics of grip of which we have any account. Since that time the disease had recurred until we might feel justified in calling it endemic, though this did not mean that it would continue indefinitely to be an affection of the large cities of the world. In previous epidemics it was noted that the disease continued to appear for a time and then gradually passed out of existence. Whether the disease exhausted the material which it might affect, or just why the cessations of virulence occurred, was not clear. One attack seemed to predispose to recurrences of the disease. It was possible that all the affections called influenza were really not the specific disease which was caused by Pfeiffer's bacillus. It was well recognized that cold itself was not the most important factor in the production of the affections that had been grouped under the designation of influenza. The worst epidemic occurred in a mild winter, and in those portions of winters characterized by higher temperature the disease seemed to be more prevalent. Dampness and fogginess seemed to favor the incubation of the agent which caused the affection. The study of influenza had persuaded the medical profession that colds were due to infectious agents. As a matter of fact colds were much more common in the lower part of the temperate zone than they were farther north, and the same was true with regard to the temperature due to altitude. It might have been expected that the severer winter of 1904 might have witnessed fewer cases of grip than the present winter, the early portion of which was mild. The statistics of New York City did not show this difference. Unfortunately the incidence of grip could not be determined, as it was not reported, and, in mortality statistics, the cause of death was usually assigned to some complications or sequela which had caused the fatal termination. As near as could be ascertained there were, during the first quarter of 1904, 176 deaths from this cause. In January there were forty-five, in February, fifty-seven, and in March, seventy-four. Comparing this with January of the present year, it was found that only thirty-eight deaths had been reported from grip, with ten so far in February. The fatal cases occurred just after the periods of mild weather. The statement had been made that the prevalence of grip as an endemic had been the principal cause in the increase of the death rate from pneumonia. It was shown, however, at the meeting of the Section on Hygiene of the American Medical Association, in June, 1904, that the apparent increase in pneumonia mortality was due to the fact that more deaths from this disease were reported under the age of five and over the age of sixty than used to be the case. There had been no increase in the death rate from pneumonia, and consequently influenza had had no effect in this way. In some parts of the country influenza had been seriously epidemic during the present year. In Chicago it had been more prevalent than at any time since the epidemic of 1891. Careful inquiry had shown that there was no such an epidemic in New York State, the New England States, or in Philadelphia. Few acute infective diseases had manifested in all times and at all places the stamp of uniformity so strongly in the aggregate of symptoms as influenza. The various epidemics had differed among themselves as regarded the course of the disease, but these differences had been found to be associated either with a particular season of the year or kind of weather, or with something special in the locality, and had not infrequently been determined by the individuality of the sick person rather than by anything in external causation.

The Bacteriology of Colds and Grip.—Dr. William H. Park said that the first difficulty that confronted us in endeavoring to understand the bacteriology of these conditions was the presence in nearly all throats of those living in New York City, of the very bacteria which were considered to be the exciting factors in grip and bronchitis. Pneumococci and streptococci were readily found in the mucus of all throats, and at this time of year influenza bacilli could be frequently isolated. It was true that during inflammations of the mucous membranes one or more of these species greatly increased in numbers and also probably in virulence, but these were matters difficult to demonstrate. During last winter, as well as during this, the influenza bacilli were only occasionally met with in cases of colds and pneumonia in December, but became more prevalent in these cases during January and February. In eight cases of colds and bronchitis examined on Tuesday of this week influenza bacilli were present in seven, but usually in less number than the cocci. Dr. Park said that it seemed almost certain that the bacteria quietly resting in our throats were capable of exciting disease when the natural resistance of the tissues was lowered through taking cold. It was also probable that these same bacteria had their virulence increased during an infection, and were thus, when transferred to another throat, more liable to excite disease than those existing in it. During an epidemic the virulence of some became so increased by frequent transfers that they might excite disease in a certain proportion of individuals, by simply finding a lodgment in the mucous membranes. The fact that the pneumococci, streptococci, and influenza bacilli were usually associated made it very difficult to decide in a given case to what organism the symptoms were chiefly due. It was generally impossible to decide from the symptoms alone what organism was the chief factor. He thought the bacteriological investigations of a case were rather of scientific interest than of practical value. A simple examination of the smear from the throat mucus was usually sufficient for a good guess as to the presence of one or more of the varieties mentioned. The examination of a blood agar plate culture of the mucus was almost diagnostic. It was probable that there were a number of varieties of influenza bacilli, and at present it was impossible to be certain whether some grouped as influenza bacilli were really of that type of organism.

Dr. T. W. Hastings said that during the past year and a half an examination of the sputum sent to the laboratory, especially from cases of acute and chronic bronchitis, and some cases diagnosed as grip, had revealed the presence of a great number of organisms. In the acute cases which ran their course with coryza, the inflammation extending down into the bronchial tubes, both streptococci and pneumococci had been found to be specially numerous, as well as that organism written about so much lately in this country, the Pfeiffer bacillus. This influenza bacillus had been found in ten cases of acute conjunctivitis, in one case of purulent vaginitis, in seven cases of acute coryza which had been diagnosed as acute influenza. In some cases of chronic bronchitis the pneumococcus and the micrococcus of Pfeiffer had been found mixed. In its morphology and stain reactions the grip bacillus resembled the gonococcus. It grew readily in plain agar, or in agar and glycerin.

Dr. Arnold Knapp said that in young infants attacked by severe conjunctivitis a form of pseudomembrane had formed, which led to a perforation of the cornea, and in these cases a microorganism had been cultivated which was identical with the influenza bacillus, and he believed Pfeiffers' bacillus would attack the conjunctiva the same as the gonococcus or the diphtheria bacillus would. In 120 trachoma cases this bacillus had been found in eight, and they had all the characteristics of the influenza bacillus. In order to compare the two organisms he obtained a culture from a true case of grip pneumonia, and the two organisms could not be distinguished either morphologically or culturally. It was interesting to note that the organism would grow only in a medium containing hemoglobin. In an examination of the grip otitides complications, as a rule the infections were found to be mixed. Among the most interesting sequelæ of eye diseases were the cases with inflammation of the optic nerve.

Dr. Warren Coleman said that in influenza the tem-

perature curve was remarkably low after the initial rise, but the intense prostration these patients experienced was out of all proportion to the virulence of the infection. He referred to two cases of marked cardiac disturbances, in both without undue elevation of temperature.

Dr. L. A. Connor spoke of the feeling of helplessness he experienced when called upon to treat these cases of grip; treatment was entirely unavailing. The bacterial findings particularly interested him, and he believed that most of the cases of ordinary colds were not cases of grip at all. He said he had been trying for three years to find a true case of influenza at the Hudson Street Hospital, but had failed. The so-called grip cases one saw constantly were not cases of influenza. He thought a sharp distinction should be made between the catarrhal colds and true epidemic influenza, and the latter was very rarely seen.

Dr. B. Sachs said that when a patient had pains in the bones and back, with an intense headache, with a sudden onset of a febrile movement lasting a few days, and then a more or less rapid subsidence of the symptoms, there was little doubt as to the existence of a disorder of an infectious nature, even in the absence of other symptoms. Disregarding the feature of cold, much more importance should be attached to the other symptoms. There was a disease, infectious in nature, prevalent in this city, with no other diagnosis than grip or influenza. He said he was struck by the fact that the sequelæ were much more severe twelve or fifteen years ago than at present; at that time he had occasion to see a number of cases diagnosed as encephalitis and meningitis due to influenza; there was nothing to distinguish these cases from the ordinary ones except possibly that the entire development and subsidence of the disease were more rapid than in those from ordinary causes. The intensity of the headaches was greater at that time than now.

Dr. Edward B. Dench said that the very severe colds or attacks of grip during the last two years had been marked by rather characteristic aural complications. In most cases the invasion had been sudden, the pain coming on without prodromal symptoms of discomfort and being very severe. There had been almost invariably some elevation of temperature, quite marked in the severer cases. Even in those cases in which the pain had lasted only a few hours there was well marked congestion of the membrana tympani, and, in severer cases, marked bulging of the drum membrane in addition to the change in color. The smears and cultures made from the discharge after incision of the drum membrane had usually shown a streptococcus or a pneumococcus infection. In quite a number of cases a mixed infection was shown, but a staphylococcus infection had been rare. One of the most noticeable symptoms in all of these cases was the early development of mastoid tenderness. This tenderness was more marked at the tip of the mastoid than over the antrum. In the majority of cases it had disappeared in the course of a few days, after free incision of the membrana tympani. He had seen this mastoid tenderness so mild as not to demand incision of the membrana tympani, and whatever effusion had taken place into the tympanic cavity was completely absorbed. It was wise, therefore, in cases of well pronounced grip infection to delay operative interference on the mastoid for a number of hours, and to observe the effect of free drainage of the tympanic cavity. He did not employ local applications of cold to relieve the mastoid congestion, as this measure simply masked the symptoms. He had found it almost invariably necessary to make a free incision of the drum membrane, in spite of the fact that the membrane had ruptured spontaneously, as in all of these cases drainage was insufficient. In cases of grip infection extensive bone destruction might occur with extreme rapidity, and might demand operative interference at a very early date. Experience seemed to teach that the only wise procedure in any case of acute otitis following an attack of grip, was to perform a free myringotomy as soon as there was well marked evidence of any inflammation within the tympanic cavity. It also taught that if mastoid tenderness persisted after this procedure, and especially if the temperature remained elevated, the surgeon should not delay opening the mastoid at once. He advocated this plan of treatment on account of the very extensive involvement of the mastoid process which had been noted, even in cases where the aural involvement had existed for only a short time. In mild cases where the aural symptoms had consisted of some slight feeling of discomfort in the ear, without pronounced pain, or where the pain had lasted but a few hours and the drum membrane had been but slightly congested or merely retracted, he had found that relief came, without surgical interference, under catheter inflation and the application of astringent solutions to the congested nasopharyngeal mucous membrane. In those cases where a serous effusion had been present in the tympanum, and where myringotomy was not necessary, the fluid had been absorbed through the lymphatics in the course of a few days or weeks. He was of the opinion that the severer aural complications could be prevented if, as soon as aural symptoms appeared, measures were instituted for the relief of congestion in the middle ear and in the nose and pharynx. The general practitioner should bear in mind the close relation which existed between the nasopharynx and the middle ear, and should treat these prodromal cases of grip characterized by intense nasopharyngeal congestion by means of local applications; in this way the number of cases of acute otitis following grip might be materially diminished in number.

Dr. Joseph E. Winters said that nothing was more difficult than to make a correct diagnosis of influenza. If a child had grip and was placed in a warm room and wrapped in blankets and kept in a free perspiration, in the majority of cases it would get well.

Dr. J. Finley Bell of Englewood divided influenza into two classes clinically, viz., those with catarrhal symptoms, and those with nervous symptoms most marked. Large doses of salicylate of sodium had given him the best results. Follicular tonsillitis had been frequently mistaken for influenza.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

193d Regular Meeting, Held February 3, 1905.

The President, Dr. Charles Stedman Bull, in the Chair.

An Extensive Epithelial Cancer of the Glans Penis Treated with the Röntgen Rays.—Dr. Robert Abbe presented a man who had been referred to him two months ago for amputation of the penis, owing to an extensive cancer involving the glans. A section of tissue which was removed and examined microscopically proved the lesion to be an epithelial cancer. About half a dozen glands in each groin were enlarged. The lesion involved a considerable portion of the glans and corona, and extended well up on the foreskin, forming altogether a large mass. Before resorting to amputation, Dr. Abbe said he thought it advisable to give the Röntgen rays a trial. Exposures of five minutes each were given twice weekly, followed in each instance by an exposure of five minutes to the rays from a Piffard lamp. After two weeks' treatment, the mass became flattened, with the appearance of apparently healthy granulating tissue, and the enlarged glands in the groin could no longer be felt. Two weeks later the cicatrization had extended in all directions, and at the present time, after thirteen exposures, there was nothing left but a small healing ulcer, which was rapidly cicatrizing. In order to demonstrate the extent of the improvement that had taken place in this case, Dr. Abbe exhibited four plaster casts colored to illustrate the appearance of the lesion as it was originally and at different stages of the treatment.

In reply to a question, Dr. Abbe said that the Piffard lamp, which he had employed in this case as an adjuvant to the Röntgen rays, was a lamp with iron electrodes, which gave a maximum of ultra-violet light, and besides

that emitted rays which in their action ionized the surrounding air, and discharged the electroscope in a manner very similar to those of radium and the *x*-rays.

Dr. Abbe said he thought there was no doubt that radium would prove effective in certain cases of malignant disease. In the case of giant-celled sarcoma of the lower jaw in a boy who had been presented at several of the meetings of the society, a cure was effected by the use of radium alone, and the patient still remained perfectly well a year and a half after beginning treatment. In another case of lupus of the forehead, with apparently beginning carcinomatous invasion, two applications of the radium caused a disappearance of the lesion, which had existed for two years, and it remained cured after more than a year. An interesting feature in connection with his case of epithelial cancer of the penis was the rapid disappearance of the enlarged glands in the groin, which were fully as large as beans when the patient was first seen. Their enlargement may have been due to simple irritation rather than to malignant involvement. The cause of their rapid retrogression must be conjectural, but it was easy to conceive that some by-product or antitoxin of the retrograding growth during *x*-ray treatment found its way along the lymphatics to the infected glands, just as the original poison had done. He had observed the same thing in malignant growths involving the axillary glands.

Lesion of the Lenticular Nucleus Found in Coal Gas Poisoning.—Dr. Walter B. James exhibited a brain section that showed very strikingly a bilateral, symmetrical softening of the globus pallidus of the lenticular nuclei. He had seen two fatal cases of coal gas poisoning during the past month, and in both of them this lesion had been found. It was first described some years ago, and was considered by some as quite characteristic of coal gas poisoning. The speaker said that while in many instances patients who suffered from coal gas poisoning recovered entirely, there were a fair number who recovered from the immediate effects of the gas, but who remained in a state of absolute lethargy and finally died, in spite of the fact that the gas had apparently entirely disappeared from the blood, as shown by the usual test. The specimen exhibited by Dr. James was obtained from a patient at Roosevelt Hospital, a man who got over the immediate effects of the coal gas, but remained in a lethargic condition from which he could be roused, but he never moved of his own accord. There was no paralysis; only slight muscular rigidity. One patellar reflex was exaggerated; the other absent. The pupils reacted slightly to light. There were no disturbances of sensation. There was a marked tendency towards the development of pressure sores, and death finally supervened. The wife of this patient, who had also suffered from coal gas poisoning, was still in the hospital, and in this same lethargic condition. In a third case, the patient passed through this stage, although she never recovered entirely. She was sent to Bellevue Hospital, where she developed certain mental symptoms, and she was subsequently transferred to the Insane Asylum on Ward's Island, where she died just seven weeks after the occurrence of the coal gas poisoning. Dr. James said that the clinical symptoms of this condition were very interesting, as was also this peculiar lesion in the brain, which appeared to be a very constant one. The occurrence of softening in this particular area had been explained on the theory that it was supplied by a small artery, a branch of the interior cerebral, which it left at such an acute angle that, in the adult brain particularly, this region was very poorly supplied with blood.

Dr. George L. Peabody thought that the anatomical peculiarity referred to by Dr. James and the comparatively feeble blood-pressure in the region of the lenticular nucleus would hardly account for the pathological condition observed in these cases, inasmuch as these influences were of such common occurrence in all cases of great lowering of blood-pressure in other pathological states, without causing this lesion. It was quite characteristic of coal gas poisoning, and had been referred to by Dr. W. Gilman Thompson in a paper on this subject presented in Washington last year, as well as by other writers.

Dr. Kinnicutt said that it might properly be asked if the characteristic nervous symptoms of coal gas poisoning could in any way be dependent upon the lesion described by Dr. James. A lesion at the particular site shown in the specimen should give no symptoms, and should in no way affect the outcome of the disease, according to Dr. Starr.

Dr. M. Allen Starr said he thought the fact was well established that the poison of coal gas attacked the entire nervous system. Cases of peripheral neuritis had been traced to it, and recent investigation had shown that a peripheral neuritis was usually associated with a degenerative process in the cells of the spinal cord, as well as in the peripheral nerve trunks. The speaker said he had no doubt that further investigation would show that in cases of coal gas poisoning the effects of the gas were not limited to these gross lesions in the lenticular nucleus, which, like the appendix, was a relic of past experience and apparently served no useful purpose. Cases of very extensive destruction of the lenticular nucleus, and especially of the globus pallidus, had been reported in which the lesion had given rise to no symptoms during life. He recalled a specimen shown by Meynert, in which both lenticular nuclei had been destroyed by cysts. The lesions were discovered at autopsy, the patient having shown no symptoms of paralysis or of a mental character during life, and the specimen was exhibited as an evidence of the fact that the lenticular nucleus could be destroyed without producing any symptoms. In ordinary cerebral hemorrhage, with destruction of the lenticular nucleus, the symptoms were due to laceration or compression of the capsule, which lay on the inner side of the nucleus, and contained all the large tracts. Dr. Starr said he had seen a considerable number of cases of coal gas poisoning, including one of those referred to by Dr. James. He was inclined to ascribe the lethargic condition of these patients to a cortical lesion rather than to the softening of the lenticular nucleus.

Dr. Peabody said that many of these patients recovered entirely after very pronounced symptoms. He recalled one patient who was comatose and had to be fed artificially through the nose for seven weeks, when she gradually became conscious and finally recovered entirely. He recalled other cases where the patients apparently had recovered and then had a relapse, and after days of increasing feebleness and indifference gradually passed into a condition of coma and died.

Specimen Showing Line of Union in the Sigmoid Flexure After End-to-End Anastomosis Following Resection of the Gut for Carcinoma.—Dr. Charles McBurney showed this specimen. The patient was an elderly man, who had an acute attack of complete obstruction of the bowels nine years ago. The abdomen was much distended, and the exact location of the obstruction could not be made out. An immediate colostomy was done by Dr. McBurney, the caput coli being opened and the bowels evacuated. Examination through the abdominal excision revealed the existence of a small tumor in the descending colon. It was deeply situated on the left side, and no attempt was made at the time to remove it. About three weeks later, when the patient had recovered from the effects of the colostomy, the abdomen was opened on the left side, and a small dense tumor was found at about the middle of the sigmoid flexure. The tumor involved the entire circumference of the intestine and was clearly a carcinoma. It was excised, together with about three inches of intestine above and the same amount below, and the divided gut was brought together by an end-to-end anastomosis. There was apparently no glandular involvement. A microscopical examination of the tumor showed it to be an annular carcinoma of the bowel, which had reduced the caliber of the intestine to one-quarter of an inch.

The patient made an uneventful recovery and remained

well up to less than two years ago, when he was killed by being shot through the head. At the coroner's autopsy Dr. McBurney secured the specimen of the bowel that had been operated on seven years previously. It showed no evidence of a recurrence of the malignant disease, and the lumen of the gut had been well maintained. No recurrence of malignant disease had taken place in the intestine or at any other point. The lumen of the gut at the point of union was very nearly, if not quite, normal in caliber. The function of the bowel from the time of operation till death had been perfect.

Cancer of the Appendix.—Dr. KINNICUTT referred to a case of primary carcinoma of the appendix in a girl of 18, operated upon six years ago. There had been no signs of a recurrence up to the present time. A little later a second case of primary carcinoma of the appendix had been reported by Dr. Prudden from the Pathological Laboratory of the College of Physicians and Surgeons.

The Surgical Treatment of Hemorrhoids.—Dr. McBurney also presented a communication with this title.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 27, 1905.

DR. HENRY S. STEARNS IN THE CHAIR.

Spinal Hemorrhage.—Dr. WILLIAM BROWNING of Brooklyn read this paper. He said that relatively few autopsies had been made on those who had died of spinal hemorrhage. A proper understanding of this condition should be based on a knowledge of the anatomy and mechanics of the local circulation. It should be remembered that the spinal cord was an elongated structure, more or less elastic, subjected to changes caused by gravity, etc., yet a thorough description was as yet impossible. The sensory and vasomotor supply was not understood in either the brain or spinal cord. The varieties of spinal hemorrhage, from an etiological standpoint, he considered under three categories, viz., traumatic, the most frequent of all; the secondary, as with inflammations or tumors, and the spontaneous, a form much disputed. All these forms occurred most frequently in the cervical region. The character and size of the cord, he said, played a minor rôle, but this region was probably more often involved because of the greater mobility of this part of the spinal column. Anatomically there were three distinct forms of spinal hemorrhage, the epidural, the submeningeal, and the myelitic. In considering the first variety he said that the blood-vessels in the epidural spaces were chiefly veins and constituted quite a plexus. Posteriorly there was more space than anteriorly; therefore, it followed that free blood would tend to collect behind the cord and dura and exert no uniform pressure upon any special part of the column. The effusion of blood here might be either traumatic or spontaneous in origin. The epidural form of spinal hemorrhage was found to be especially common in the new born. The correctness of current teachings upon certain points was verified in a collection of ten cases. He said it was a common teaching that the meningeal form of hemorrhage was more painful, but the epidural cases exhibited pain quite frequently. In nine out of these ten cases there seemed to be a sudden onset of the symptoms, due to rupture of aneurysms. The epidural cases should be distinguished from the meningeal forms. The loss of control of bladder and rectum, the motor paralyses, etc., were not considered by him. In these forms there was far less tendency to impairment or loss of sensation than in the myelitic forms. In those cases in which the blood collected by reason of the anatomical arrangement in the posterior part of the spinal canal there was hope from operative interference. The submeningeal form of spinal hemorrhage he divided into three classes, the subdural, the subarachnoidal, and the subpial. The first of these was comparatively unimportant, as also was the second. The subpial form gave rise to positive manifestations, yet it seemed to be impossible to get a true type because these cases were so largely associated with other cord troubles. Hemorrhage into the cord itself, or the form classed as myelitic, he divided into three divisions, the central or tubular, the punctate or multiple or capillary, and the focal forms. The central or tubular form occurred with the blood infiltrating longitudinally and more often resulted from injuries, such as fractures or dislocations, when the vessels would be torn across. This form had been subjected to special study within recent years. The second form referred to was usually associated with inflammatory processes. The third form, the focal, was the one that corresponded to the ordinary forms of spinal hemorrhage and he reviewed briefly the literature on the question whether these were primary or secondary in origin. It was surprising how many of the cord cases began before the period of life when cerebral hemorrhage was most frequently encountered. Among twenty cases noted there were only six that occurred in persons over 45 years of age. Fourteen of these cases were in males and six in females, probably showing that myelitic hemorrhage was not so much due to a degeneration as to active conditions of life. Where there were such complications of spinal hemorrhage as inflammations, fractures, dislocations, decubitus, etc., the outlook was correspondingly affected. In the submeningeal forms the complications had little independent significance. In the myelitic forms they were not rapidly fatal unless they occurred above the origin of the phrenic nerve. The course of lymphatic absorption was upwards, and therefore absorption went on slowly. Dr. Browning then gave a detailed history of a case.

Dr. F. W. TILDEN reported the microscopical findings in the case detailed by Dr. Browning.

Dr. HARLOW BROOKS reported a few cases and demonstrated the microscopical findings with the stereopticon.

Dr. EDWARD D. FISHER said that spinal hemorrhage was not so common as many other diseases of the spinal cord, and we were not so familiar with it. A point he wished to emphasize was his belief that diseases of the blood-vessels were a frequent cause of spinal hemorrhage, such as arteriosclerosis, and the same diseases of the blood-vessels would lead to the same conditions in the cord as they were found to lead to in the brain. Spinal hemorrhage was more often due to traumatism. In caisson disease there was also a traumatic lesion. In looking over the literature and considering the classes of cases that presented themselves to his observation, he thought it better to divide these cases of spinal hemorrhage into two classes, the subdural and the intraspinal, the first including those cases Dr. Browning classed as epidural. In the epidural class he thought one obtained greater evidence of local injuries which might be a guide in diagnosis. It was not an easy matter to make a differential diagnosis between the subdural and intraspinal forms of spinal hemorrhage and at times almost impossible, at least at first. In the majority of these cases there were associated fractures of the spinal column. It was not a common thing to get an intraspinal hemorrhage without getting evidences of fracture of the spine itself. In making a differential diagnosis between subdural and intraspinal hemorrhages one could be guided somewhat by the fact that subdural hemorrhage would present greater symptoms of pain, which pain might be distributed through the extremities; the pain was not due so much to any lesion of the cord, but was probably due to pressure upon the posterior spinal nerve roots. This could also be obtained from hemorrhage into the substance of the spinal cord. The course of the blood naturally proceeded along the lines of least resistance, and therefore in most instances the hemorrhage was found in the gray matter of the cord. It was not necessarily, only usually, so unless the lesion was a destructive or a transverse lesion. Most often one-half the gray matter would be involved to a greater extent than the other one-half.

Ordinarily one would find the symptoms of a transverse myelitis present. The lesion might again be con-

fined almost entirely to the anterior fibers of the cord. Dr. Fisher closed with the statement that, in the majority of cases, the hemorrhages encountered were intraspinal and not subdural. If the lesion was intraspinal no operation could relieve the condition; if subdural, there was some hope from operation. In many cases of fracture of the column or injury to the spine, he was in favor of operation because the operation itself would relieve pressure. If there was no fracture or injury to spine he would not advise any operative interference.

Dr. Pierce Bailey said that in studying spinal hemorrhage it was necessary to know whether we were dealing with the traumatic or the idiopathic variety. The idiopathic forms he considered to be extremely rare, and the correctness of diagnosis was always open to question. There were many forms of myelitis which began in the same manner as we expected to find spinal hemorrhage. He did not believe that cases of hematomyelia occurred except where there was present degeneration of blood vessels. Among the old people at the Alms House very few cases of paraplegia occurred. He referred to the important complications of syphilis, and here thrombi were more common than hemorrhage, and constituted a more important factor of spinal syphilis. In traumatic hematomyelia there were two classes, first, those in which the hemorrhage occurred independent of injury, and, secondly, those that occurred secondarily to crushing injuries, fractures, dislocations, and the like. In these latter cases the hematomyelia was apt to be associated with mutilations of the spinal cord. The question of hemorrhages occurring outside the spinal cord, he said, was a very important one from the surgeon's point of view, because the surgeon would be glad to operate.

Dr. George W. Jacoby said that nearly all the cases of spinal hemorrhage met with were in the spinal cord itself, and nine-tenths of them were due to traumatism. He said that if lumbar puncture were done, and one were sure that a vein had not been punctured, and one should withdraw blood mingled with cerebrospinal fluid, it would be fairly certain that one was dealing with hemorrhage. In many cases the hemorrhage into the cord was very little, and many of these cases were diagnosed as hysterical. In these cases one found atrophy of groups of muscles, wasting and fibrillation of muscles, reflexes of single muscles lost upon one side, and certain objective signs would be present, showing that one was dealing with a slight hemorrhage in the cord. These cases were the important ones from a medicolegal point of view as well as from a professional one. Syringomyelia following hemorrhage was very uncommon; still, he said, it did occur.

Dr. William M. Leszynsky said that the idiopathic variety of spinal hemorrhage was very difficult to prove, and he believed that all cases were due to direct traumatism or secondary to injuries of the spinal column itself. If one made a diagnosis of intraspinal hemorrhage the prognosis, as a matter of course, was bad. One did not expect, when the damage to the cord was great, to have absorption prove of value. But if it was due to a dural hemorrhage one could hope for absorption to take place. Operation, therefore, in these cases, would be of no value. He said that he had recently performed a lumbar puncture in a case of spinal hemorrhage resulting from traumatism in the lumbar region; this case had all the symptoms usually attendant upon such cases. Blood was withdrawn, not with the idea of curing the patient, but to relieve the pressure that was present. The patient was improved, but made no recovery, paraplegia still persisting.

The Open-Air Treatment at Home for Tuberculous Patients, with a Description of a Window Tent and Half Tent.—Drs. S. A. Knopf and W. B. McLaughlin presented this communication, which was read by Dr. Knopf. He said that the modern object of phthisiotherapy was to give the tuberculous patients the greatest amount of pure, fresh air for the greatest possible number of hours in the twenty-four. This constant exposure to the fresh, pure air was, of course, obtainable in an ideal way in the specially constructed sanatorium, where the patients reclined on comfortable chairs in the open rest-cure gallery during the day, and the beds were moved onto the open veranda at night. To provide the same advantages for the large number of consumptives who could not go to a sanatorium many appliances had been devised. In country homes suitable extensions could be made with relatively little expense, or, where this was impracticable, a so-called sleeping shack could be built, which would have a southern exposure. It could then serve as a rest-cure gallery by day and an open air sleeping place by night. In large cities, particularly among the poor, the flat roof and the fire-escape had been employed. He did not recommend the fire-escape, but said that a steamer chair placed upon the roof would answer the purpose of a typical reclining chair, and a large umbrella would serve as a protective awning. For patients who had a yard or a convenient flat roof, a half tent, which he presented, would prove very suitable. This half tent was composed of steel tubing, over which strong sail duck was stretched and secured by snap buttons. To prevent the tent from being overturned by the wind it was secured by ground spikes. He showed a model of a reclining chair, intended for outdoor use, made of bent enamel steel tubing with woven wire springs top and back. This chair was adjustable. The half tent and chair should be placed as nearly as possible so that the patient could be exposed to the sun and at the same time be sheltered from the wind. It was his conviction that nothing increased the patient's chances for recovery as much as sleeping at night in a pure, cool atmosphere. He presented a device which could be used in a tenement house as well as elsewhere. This window tent was an awning which, instead of being placed outside the window, was attached to the inside. The patient lying on the bed, which was placed parallel with the window, had his head and shoulders resting in the tent. The frame, which was attached to the awning, was placed in the lower half of the window, which it did not completely fill, a space of about three inches being left for the escape of warm air from the room. This space could be reduced according to the needs. The patient entered the tent through a flap on either side of the tent. The lower edge of the canvas was long enough to be tucked well under the mattress, so as to exclude the air from the room and protect the patient from draughts. He showed that ventilation in this tent was perfect. There was also a protruding portion which would be found useful in protecting the patient from storms. It was best to arrange this peak with hinges, so that it could be folded down so as to facilitate the closing of the window when desirable. The advantages of this device were that the patient's body was kept thoroughly warm and that he received the air only in his face. The cot could be placed by the window to suit his preference for sleeping upon the right or left side. Again, this arrangement would not attract the attention of outsiders. The bed could be placed alongside the window instead of at right angles to it, which was an advantage in small rooms. It was necessary to raise the bed to the level of the window sill, but this could be done with but little expense. The frame of the tent could be made to fit any window, and could be moved away during the day time, or if it was necessary to remain in bed during the day time, the tent did not interfere with the comfort of others using the same room. In winter time the patient could be covered with enough blankets to secure absolute comfort. Where blankets were a scarcity, a number of layers of newspaper between the coverings added greatly to their warmth. When the light awakened the patient too early, he could wear some thin, dark colored material over the eyes. The pulmonary patient should be in communication with the person who took care of him by means of a bell. He should also have a cuspidor, or, better, a pocket flask, which he could keep under his pillow. Dr. Knopf exhibited his latest model, which differed from the former in its greater simplicity and durability. It was oval, 2½ by

2¼ inches, and was made according to the principle of the non-reversible inkstand. A urinal should also be convenient, so that the patient need not leave his bed. It was always to be borne in mind that the more pleasing and entertaining the outlook from the veranda or rest-cure gallery the better for the sufferer. Lying for hours and hours, even in the open air, had resulted in some cases in hypostatic congestion of the lungs; the patient should change his position from time to time and take frequent deep inspirations. The afebrile patient should have some mild exercise. The amount of this exercise should be determined by taking the rectal temperature before and after exercising. A temperature of 100° was an indication for absolute rest. The patient should be gradually accustomed to the exposure to night and day air. He should first be placed in a reclining chair before the open window during the warmest part of the day, and the number of hours of exposure to the open air gradually increased until after a week or ten days he might begin with a few hours' sleeping in the window tent. Dr. Knopf emphasized the importance of the tuberculous patient dressing, undressing, taking his massage and hydrotherapeutic applications in a room with a temperature of at least 72° F. He thought there was no region in the United States where this open-air treatment could not be carried out with advantage.

Dr. H. P. Loomis said all agreed that cold, fresh air was good for consumptives, but that, in this climate, it was difficult to provide because of the extremes of weather and sudden changes. The cold wintery days here precluded such exposures, and he would dislike to see the general tone of the profession favoring the ideas of extremists, sleeping and spending the time out of doors. He thought this sleeping out doors was becoming more or less of a fad. Sleeping out of doors on verandas, etc., under clear, cold climatic conditions was all right, but not in New York City. The plan of sleeping in the room with a tent, as demonstrated by Dr. Knopf, especially when other people must live in the same room, he heartily approved of. He said he was watching with much interest the plan that was being carried out at Bellevue by the trustees. About eighty cases were under observation during the past year, and the results showed that they had gained in weight, and their general improvement had been extraordinary. Still, to him, it was a question whether it was the cold air that caused such marked improvement; the cases were selected ones; they had the best of attention and were watched most carefully; they were educated to care for themselves; their surroundings were made most agreeable, and much of the treatment employed was independent of the fresh air.

Dr. J. Blake White said that the tuberculous patient required treatment that was adapted not to a single entity claiming attention, but to a series of pathological conditions. He commended Dr. Knopf for what he had done in alleviating the sufferings of the consumptive poor. He believed that home treatment of these people, when properly carried out, could give as good results as the sanatorium treatment.

Dr. John H. Huddleston emphasized the importance of the practical suggestions that were made by Dr. Knopf. One who had followed the tuberculosis problems increasingly was certain that these patients must be treated at home, and if they were to be cured at all, it was there that they would be cured—at home. With the importance of home treatment borne in mind, it was easy to see that any device for home treatment of consumptives that was practicable and applicable was of far more importance than the consideration of climatic changes. Ventilation and warmth for the room were impossible to obtain without practically turning the room into a flue, and this provision seemed to be admirably adapted to overcome such objections in the device submitted by Dr. Knopf. Practically the room was turned inside out—making part of the room outdoors. It should not be forgotten that the outdoor treatment might be carried too far in some cases. The method itself, though, seemed to be correct in the arrangement of air currents.

Dr. Wm. T. Klein spoke of the results that had been obtained at the Riverside Hospital, on North Brother's Island, where the air was far more dust-free than in the city proper. The cases were advanced ones, some far advanced, that were sent there by the Health Department in order that they might not be a menace to the city. An incipient case was rarely received. A moderate number of cured patients were discharged, and more cures would have been added to their number if the patients could have been kept longer under observation. The treatment consisted essentially in hyperaëration, hyperalimentation, and respiratory exercises. The exercises were given only to afebrile patients, and with marked improvement in their chest capacities and in the dyspnea. Out of seventy-seven advanced cases only seven complained of night sweats at all, and those were very moderate. About 60 per cent. of these patients gained in weight an average of eight pounds. One gained forty-eight pounds in seven months. The medical treatment was symptomatic. These patients were encouraged to go outdoors.

Dr. Lazarus Zwisohn and Dr. Westcott also discussed the paper.

Dr. Knopf closed the discussion.

Recommendation of the Comitia Minora.—Dr. A. Jacobi said that the Comitia Minora had recommended that a committee of three be appointed by the president to oppose the bill legalizing and regulating Osteopathy, such a committee to provide suitable resolutions, which should be presented at a meeting of the society.

The president appointed as members of this committee, Drs. M. L. Foster, Thomas, and J. Gardner Smith.

Against Kinesipathy, Osteopathy, and Optometry Bills.—Dr. M. L. Foster offered a resolution, which was unanimously carried, that the County Medical Society protest against the passage of the bills to legalize and regulate the practice of kinesipathy, of osteopathy, and of optometry, because each bill was an attempt to evade the laws of the State; also that no license to practise any portion of the healing art should be granted to such men unless they had the proper training required by the present medical laws.

Chicago Medical Society.

At a meeting, held February 22, Dr. Otto J. Stein read a paper on "The Dunbar Antitoxin Method of Treating Hay Fever." He reported 26 cases. To obtain the greatest degree of immunity, it had been his experience that the remedy must be applied before the onset of an attack. At the very first sign, or just prior to the time when the attack was expected, and this time was fairly well known by those who suffered from this disorder, resort should be had to the medicine. When the disorder was once fully established, he had learned from his patients that they did not obtain the relief expected. It therefore was his invariable custom to emphasize to his patients the necessity of using the remedy at the very onset of the disease. Regarding the remedy, therefore, more as a prophylactic one, he had found that in all but three of his cases it proved efficient. When used during the height of an attack, it usually modified the severity of the same, but never entirely relieved the patient. The experience of some observers had been that even a well-developed attack might be relieved at once and entirely; but such had not been his experience. Dr. Joseph M. Patton read a paper on "Tricuspid Obstruction," and reported a case associated with the mitral and aortic lesions. Dr. William F. Waugh read a paper in which he reviewed Sajous' work on "The Internal Secretions." He said that this book must be reckoned with; that it ought to be carefully studied and vigorously opposed, in order that the measure of truth it contained might be clearly brought out, and its errors recognized and eliminated before they became crystalized in the working theories of the profession.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 11, 1905:

	Cases.	Deaths.
Measles	349	10
Diphtheria and Croup	296	26
Scarlet Fever	270	19
Smallpox	1	.....
Chickenpox	159	.....
Tuberculosis	480	183
Typhoid Fever	30	9
Cerebrospinal Meningitis	.....	76
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.....
Totals	1,585	323

The Recti in Relation to Hernia.—Landau draws attention to the fact that when straining efforts are made after expiration, the recti muscles broaden out and their outer edges are pushed sidewise over the inguinal regions, so as to form a very considerable addition to the strength of these defects in the muscular wall. After inspiration, however, the recti are unable to become wider, and the inguinal openings are left unguarded. It is customary to take a deep inspiration and close the glottis before exerting any muscular force, because in this way sufficient oxygen is furnished to last for the next few moments when no respiratory movements are made, while the distended chest also affords a better hold for the muscles of the upper extremity. It would be well for those having a predisposition to hernia to train themselves to reverse the usual procedure and to make straining efforts, sneeze, etc., only after emptying the lungs, as in this way the recti would be made to give support to the weak inguinal canal.—*Zentralblatt f. Chirurgie.*

The Duration of Human Pregnancy.—Blau and Christofoletti examined the records of the obstetrical clinics of Schauta and Chrobak for the years 1892-1901, comprising 68,032 births, in order to determine the correlation of large children and protracted gestation. Among this number 1,778 of the children weighed more than 4,000 g., and in 150 of these pregnancy had lasted over 300 days, and in 135 over 302 days. These figures are closely in accord with those obtained by V. Winkel and Füth, and lead the authors to conclude that gestation may be protracted beyond the legal three hundred and two days, and that the delay occurs more often with large children than with those which do not pass middle size.—*Monatschrift f. Geburtshülfe u. Gynäkologie.*

Tuberculous Adenitis Treated by the X-Ray.—G. E. Pfahler believes that in the crusade against tuberculosis one of the most important points of attack is that of tuberculous adenitis. The *x*-ray treatment is giving better and better results. Bullitt has collected 226 cases that were subjected to this method, with the following results: Seventy-nine, or 35 per cent., were cured; 92, or 40 per cent., were improved; and 55, or 25 per cent., were unimproved. Even if no more cures can be reported from the use of this method than by surgical methods, the scar is avoided, and that is a distinct gain. The writer concludes that although it is too early to estimate the chances of recurrence after *x*-ray treatment, still it offers the best cosmetic results; the danger of secondary involvement or dissemination is lessened; suppurating glands should be incised and drained, and then subjected at once to *x*-ray treatment; cases should be treated as early as possible. The writer has had two cases which have remained well for a year.—*The Therapeutic Gazette*, January 15, 1905.

Rupture of Gall-Bladder (Spontaneous and Traumatic, Operative and Nonoperative). An Historical Review of 203 Cases.—Benjamin Merrill Ricketts classifies the cases which he reports into the spontaneous and the traumatic rupture, and these he separates again into four divisions. He mentions 37 cases of spontaneous rupture of the gall-bladder, which have been operated upon successfully, and shows that 80 per cent. of these have been females; that one or more concretions have been found in 72 per cent. of them, and that 80 per cent. of these successful operations have been cholecystotomies. In another group of 27 cases in about 60 per cent. of which concretions were found, operation was successful. As to sex, there was a predominance of neither. Of the unsuccessful operations, 80 per cent. were abdominal sections. In other groups, 6 recovered without operation, while 89 died without operation, concretions being found in about 60 per cent. To sum up, 58 per cent. of those operated upon recovered, while only 6 per cent. of those not operated upon recovered. Of the traumatic cases, 23 of those operated upon recovered, while 3 died. Fourteen died without operation, peritonitis being the general cause. Four cases recovered without operation, probably from drainage. Of the cases of traumatic rupture, 88 per cent. of those operated upon recovered, while 22 per cent. of those not operated upon recovered.—*St. Louis Medical Review.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended March 11, 1905:

MANUEL GARCIA: TEACHER, DISCOVERER, AND MAN.*

BY JAMES E. NEWCOMB, M.D.,
NEW YORK.

THE spirit of scientific medicine has ever been that of a true eclecticism. Its motto has been "Truth against the world." From every quarter it has sought truth and appropriated it wherever found. It learned from a monk, as Dr. Holmes reminds us, how to use antimony, from a Jesuit how to cure agues, from a friar how to cut for stone, from a soldier how to treat gout, from a sailor how to keep off scurvy, from a post-master how to sound the Eustachian tube, from a dairy-maid how to prevent smallpox and from an old market-woman how to catch the itch insect. To this unique enumeration let it be added that half a century ago it learned from a teacher of singing the perfected art of examining the interior of the larynx. From this period dates the renaissance of our knowledge of diseases of this organ and of contiguous structures.

During the present month the minds of laryngologists the world over have had but one Mecca, a modest house shaded among the trees, back a little way from one of the streets of Northwestern London. The gate-post bears the modest inscription, "Mon Abri" (my shelter). Here lives Manuel Garcia, who has to-day completed one hundred years of an eventful, happy and useful life. To have lived this long span of years is a remarkable event; to have lived it during most of the nineteenth and the opening years of the twentieth century is a unique distinction, and it is a matter not only of congratulation to him, but of gratitude for ourselves that the century's roll call finds him with mind alert, with eye undimmed and with natural force but little abated.

Garcia was born at Madrid, and in his veins runs the blood of a remarkable Spanish family made up of men who have been well-characterized as "representative artists whose genius and originality have left a permanent trace on the records of vocal execution and adornment." His father, who was born in Seville in 1775, and died in Paris in 1832, was Manuel del Popolo Vicente Garcia and his mother Joaquina Sitchex, a well-known dramatic artist of her day. Genius was prodigal in her distribution of talent to the children of this union. Two daughters may be particularly mentioned; one, Marie, afterward became the celebrated Madame Malibran (died in 1836), and the other, Pauline, who was afterward Madame Viardot-Garcia. Both of them were among the world's most famous singers. The latter is now living in Paris at the age of eighty-five years. The parents removed a few years after Manuel was born to Paris and later to Naples, leaving him in Spain, but he joined them in Italy in 1815. His musical education began with instruction in harmony by Fétis, a noted teacher of the time, and in singing by his father. It is interesting to know that for a long time the boy desired to become a sailor and that he was dissuaded with considerable difficulty from following out this plan. With his father he came to America in 1825. The senior Garcia, who had reaped many musical triumphs in European capitals, had formed the scheme of establishing Italian opera in this country, and the journey was undertaken in furtherance of this idea. Eleven new operas were given here in the course of a single year, and the journey was then extended to Mexico, where the company met with great success. Just as they were about to leave for home, a grievous calamity befell them. Near Vera Cruz they were attacked by brigands who robbed the father of all he possessed, including nearly thirty thousand dollars in gold, and the knights of the road added insult to injury, for after despoiling him of his goods they compelled him to sing for their entertainment.

Garcia the son retains very distinct recollections of this American journey. He was greatly interested in our city and explored it thoroughly. His nautical instincts were still in evidence, for he told a recent visitor with considerable glee how, when he was one day walking along the battery, he was invited to go out sailing. He accepted with alacrity, but the boat was small and the weather squally. Soon the craft was upset, but he managed to crawl up on the bottom of the boat, whence he was rescued, none the worse for the experience. Had timely assistance not been at hand, the development of laryngology might have been long delayed.

For some years he was a professional singer, having a tenor voice, but in 1829 he gave up the stage and began to devote himself entirely to teaching. In this work he seems to have been, from the start, preeminently successful. He busied himself particularly with the study of the conformation of the vocal organs, the limits of the voice registers and the mechanism of singing. In 1835 he was appointed Professor of Singing at the Paris Conservatoire, and removed from Spain to that city. In 1840 he presented to the French Academy his "Memoire sur la Voix Humaine," which secured for him the congratulations of this body and which may rightly be said to form the foundation of all subsequent investigations of the voice. In 1847 he published his "Traité complet de l'Art du Chant," which was speedily translated into French, English, and Italian, and gained for its author a world-wide reputation. In 1850 he resigned his position in Paris and removed to London, where he has since resided and where he was for many years a professor at the Royal Academy of Music. He was now in the front rank of teachers. Many of the world's most famous vocalists were among his pupils. Among them may be named Jenny Lind, Henriette Nissen, afterward Madame Salamon, Santly, Antoinette Sterling, Johanna Wagner and Bataille; also two of the best known teachers, both still in

*Paper read at the Garcia Jubilee meeting of the Section on Laryngology, New York Academy of Medicine, March 17, 1905.

active work, Madame Marchesi and Julius Stockhausen.

But the event which has rendered his name imperishable was yet to come, and this brings us to the achievement which links his name with our own profession.

From the earliest times physicians had naturally been desirous of seeing the interior of the human body and of watching as far as possible the workings of its organs. Beginning with Bozzini in 1807, a long series of earnest and conscientious men had sought to view the interior of the larynx during life. A vast amount of apparatus had been constructed with this end in view. Most of it was cumbersome and all of it was unsuccessful. Glimpses had been had of the laryngeal vestibule and occasionally of the posterior commissure, but no satisfactory view of the true cords or sub-glottic structures. Most of the apparatus pushed the tongue and epiglottis before it so that the orifice of the larynx was more or less occluded. Illumination was poor and the importance of the protrusion of the tongue was not appreciated. But progress was being slowly made by different men in different countries. Time does not permit us to call the roll of these investigators. The story is a fascinating one, and the details of it are easily accessible. Among those thus engaged was the teacher of singing in London. As far as we know, he was not aware of what had been done by others. He had often thought out the theory of laryngoscopy, but believed it impracticable. In September of 1854 he went to Paris to spend his holidays, and while there took up the subject anew and brought it to a successful issue. He was his own subject, and is, as far as we know, the first man who ever conceived the idea of an autoscopic examination, and the first one who fully saw the interior of the larynx in action.

Fortunately, we have on record the master's own words with reference to this epoch-making event. "One day in September, 1854," he says, "when I was sauntering about the Palais Royal, busied with the wish often put aside as unattainable but yet always urgent, namely, to see the glottis during the act of singing, I suddenly saw both mirrors of the laryngoscope in their respective positions as clearly as if my eyes actually beheld them. I immediately hastened to Charrière, the instrument maker, and in answer to my inquiry if he happened to have a little mirror on a long handle, he replied that he had a small dental mirror which had been exhibited in the London exposition of 1851, but which had been found unpractical. I bought it for six francs. After procuring a small hand mirror, I hastened home in great impatience to begin my experiment. I laid the little mirror, which I had warmed in hot water and carefully dried, on my uvula, and with the hand mirror concentrated a beam of sunlight on its surface. To my great joy, I saw the glottis widely open and so distinct that a portion of the trachea was visible.

"When my initial excitement had subsided, I began to examine what was presented to my eye. The form and manner in which the glottis opened and closed noiselessly and its movements in phonation filled me with astonishment.

"From my observations, the conclusion easily followed that the theory ascribing to the glottis alone the capability of tone production was completely vindicated, from which it further followed that the cervical tissues in front of the larynx had no share in tone production, although they in common with variations in position of the soft palate and changes in shape and space relations of the pharynx could modify it. In these changes we find the possibility of varying what we style the timbre or tone-color of the sound."

Garcia soon returned to London, and on March 22, 1855, presented to the Royal Society of London his memorable paper entitled, "Observations on the Human Voice," in which he accurately described the action of the vocal bands in inspiration and phonation, adding important considerations on sound production in the larynx and on the formation of chest the falsetto notes. His own introduction to this description is characteristically modest. His paper opens as follows: "The pages which follow are intended to describe some observations made on the interior of the larynx during the act of singing. The method which I have adopted is very simple. It consists in placing a little mirror on a long handle suitably bent in the throat of the person experimented on against the soft palate and uvula. The party ought to turn himself toward the sun so that the luminous rays falling on the little mirror may be reflected on the larynx. If the observer experiment on himself, he ought, by means of a second mirror to receive the rays of the sun and direct them on the mirror which is placed against the uvula."

The "little mirror fixed on a long handle suitably bent" has revolutionized the study of laryngeal disease.

As often happens under similar circumstances, the importance of Garcia's results was at first hardly appreciated. Some thought his success due to merely the fact that he had the peculiar ability of supporting in the pharynx the prolonged contact of a foreign body without the provocation of attempts at vomiting. The idea that a new method had come to light which with patience and the training of the subject was of universal applicability rooted slowly in the minds of men. But the work of Türck in Vienna and of Czermak in Budapesth soon made the importance of Garcia's work clearly manifest. To the latter we owe the suggestion of wearing the reflecting mirror on the forehead. Unfortunately, an unhappy controversy arose between the partisans of the two men just named as to their respective shares in popularizing the new method of examination, but the development of the story from this point on is without the scope of this paper.

No data have come to the writer's knowledge as to the time at which Garcia gave up his active work as teacher. Gradually from the confusion of conflicting claims his own work stood out in its true light. To-day we look to him as the originator of the art of practical laryngoscopy. In the sunset of his life his work has been fully recognized, and due honors have been showered upon him. With the medical profession his relations have always been most cordial and he has been chosen an honorary member of various of its societies. In 1880 he was elected Honorary Fellow of the American Laryngological Association, the late Sir Morell Mackenzie being the only other man admitted to this class of Fellowship.

No reference to his later years would be complete without mention of the marvelous preservation of his mental and physical powers. Many men of seventy-five hardly rival him in these respects. Though somewhat bowed with the weight of years, he is able to go about and goes out frequently, though becoming easily tired when walking. He participates in many of the activities of life and takes a lively interest in the events of current history. He attended a recent meeting of the Laryngological Society of London, and in a firm, clear voice participated in its discussions. He greets the visitor in a charming, cordial and hospitable way. His conversation betokens a vigorous mind and is enlivened with flashes of quaint humor. He is in every way a delightful man to meet. He speaks fluently English, French, Spanish, Italian, and some German. Now, in his de-

clining years, surrounded by a host of loyal friends and the object of their love and veneration, he has this day received a tribute which has come to him from all lands wherein scientific medicine abides, a tribute which any man might well envy.

In a treatise on old age, written centuries ago by one whom we call a heathen but whose thoughts and words are immortal, Cato thus discourses to his friends Scipio and Laelius: "As I love to see the fire of youth somewhat tempered with the gravity of age, so I am equally pleased when I observe the phlegm of age somewhat enlivened with the vivacity of youth, and whoever unites these qualities in his character may indeed have the marks of years in his body, but will never discover the same in his mind." Manuel Garcia is to-day a glorious exemplar of this ideal.

RADIOTHERAPY AND SURGERY, WITH A PLEA FOR PREOPERATIVE RADIATIONS.*

By WILLIAM J. MORTON, M.D.,
NEW YORK.

The Röntgen ray was first a matter of interest to pure science, then to surgical diagnosis, and lastly to general therapeutics. One feature of its advent into therapeutics was somewhat sensational, for it was claimed that it would cure cancer. This claim has naturally been found to be too broad. True, it can cure cancer of some types and in some stages, but equally true it cannot cure cancer of other types and in other stages. Sufficient experience has now been gained to enable an expert to judge of what cases he can fairly undertake and what not, or again, to judge in what cases the *x*-ray may be helpful to the patient, with or without conjunction with other measures, and in what manner helpful. And we must not forget, furthermore, that Röntgen therapy has created a field of usefulness all its own in many other diseases; if its use should, at this moment, be abandoned for treatment of cancer, it would still retain a transcendant place in therapeutics.

The discovery of radium in 1903 brought a new ally to radiotherapy. We may now, at this date, fairly ask ourselves, What may be expected of these two radiations therapeutically? We may look at this question of status from three points of view: (1) The nature of the radiations; (2) their effect upon tissue; (3) their effect upon disease.

1. *The Nature of Röntgen and Becquerel Radiations.*—A radiation is an effect exerted radially across space. Newton's idea of light was that it was propagated by means of tiny corpuscles shot forth from the emission source at infinite velocity. But it was difficult to conceive of transmission of energy unless by aid of a medium, and hence an all pervading ether became an hypothetical necessity. With this granted, the undulatory theory of light became established. Faraday and Maxwell extended this undulatory view of electricity, and Hertz finally actually measured the length of electric waves, and otherwise demonstrated that light and electricity are electromagnetic phenomena of the ether. Science had just become reconciled to the novel fact that electric currents were not like fluids traveling in a wire or conductor, but were in reality propagated at the speed of light in the nonconducting material around the wire, when the marvelous phenomena of uranium and radium radiations appeared.

Now, no longer is the radiation undulatory; it is, on the contrary, corpuscular. The ether pulse or wave will explain the gamma rays, but not the alpha and the beta. We must lay aside our old idea that the chemist's atom is the smallest demonstrable subdivision of matter, and must accept the fact that his atom breaks up into thousands of smaller particles flying off at a speed of from 20,000 to 160,000 miles per second. We have here simply a disintegration of the hitherto accepted atom and the liberation of its latent energy. The shot off beta particles are known to be negative. Whether each atom is matter plus a negative charge, or simply a unit of negative electricity alone, is not yet determined.

I have touched thus cursorily upon these facts to point out that our therapeutic radiation is thus twofold, namely, undulatory, when we use the *x*-ray or the gamma ray of radium, and corpuscular when we use the alpha and the beta rays of radium.

There exist then two theories of electricity to-day, one the corpuscular, the other the undulatory.

Our radiation treatment is therefore (*a*) a bombardment of positive particles (alpha rays); (*b*) a bombardment of negative particles (beta rays); (*c*) a penetration of rays like light (*x*-rays and gamma rays).

In the one case a swarm of corpuscles negatively charged stream through tissue as air streams through a coarse-meshed sieve; in the other case beams of light stream through as does sunlight through a pane of glass; in both cases the tissue absorbs the new energy. But the radiation energy is not lost; it is merely transformed into heat, chemical and other forms of energy. The result is a physical impairment of the integrity of tissue, a corresponding physiological change, and an effort of nature to repair the damage, whose success depends upon the degree of injury. If the injury be too great, degeneration or necrosis ensues, if in reason, repair of the damage sweeps along with it repair of the disease, just as an irritating zinc solution sets up in a conjunctival membrane a primary inflammatory process, whose consequent tissue restoration carries with it a repair of the initial diseased conditions.

Effect upon Tissue.—Whether undulatory or corpuscular, these radiations exert many effects in common.

They penetrate all matter in proportion to its density. They ionize the air, that is to say, they tear asunder joined atoms and provide both positive and negative carriers of electricity, which latter thus make the air a conductor. In penetrating living tissue they produce electrical, chemical, and inflammatory effects. It is some one or any of all of these effects which cure or fail to cure disease.

Pathological effects observed are mainly upon the walls of the blood-vessels. The endothelial lining or intima is caused to degenerate, an endarteritis obliterans ensues, and the nutrition of the part fails (L. Freund). The epithelial matrix of the nails and the seminal vesicles are easily affected and also the hair follicles and sweat glands. The most obvious effect of excessive radiation is therefore to set up degeneration. This is the view of Scholtz, who believes that the cells of the connective tissue are especially affected. But *pari passu* the radiation may not be excessive, the result is stimulatory, and nutritive activity is augmented. We may use heat in the same manner; we may burn enough to set up degeneration and necrosis, or may apply just enough heat to set up nutritive reaction.

Technique.—We refer only generally to this point here. The disposition to-day is to use radiations of less intensity than formerly. Some early cases of epithelioma were *x*-rayed to produce a "caustic effect." To be sure, no one followed this technique. A common practice a year ago was to *x*-ray to the

*Read before the Harvard Medical Society, January 7, 1905.

point of a severe dermatitis, namely, a second stage with formation of vesicles and serous effusion. To-day a mild dermatitis for the first series of sittings only is allowable. Again the *x*-ray was employed over a long period of time, viz., so many months. It is now a question of carrying the *x*-ray sequences of sittings along to a maximum in four to six weeks, and then of allowing an interval of half this period of time at least to watch for repairs or cure.

It is a sad fact that one may carry the treatment of a facial epithelioma steadily up to a point of complete cicatrization and cure, and then by prolonging treatment see the entire area break down again into a condition worse than at the start. The moral of this experience is to know when to stop the applications, and also in this class of cases not to *x*-ray except gently. Experience had to be gained, and it is now gained, in many instances.

The main feature of a successful technique is to standardize, *i. e.* to measure accurately each step of the administration. For my part, I pursue a steady cumulative treatment, each step of advance the same as the last one, until an end result judged of by the skin reaction is reached.

I think this is best accomplished by a hard tube (5-inch and over, alternate spark gap); about three to four amperes in a primary circuit at 60 volts; nine inches distant from the target; 18 minutes' exposure three to four times weekly. By actually pursuing this plan, a serious burn is impossible, the usual dermatitis is reached with great regularity in about three weeks; its intensity can then be diminished, maintained or increased at will, and the case thus be held in rigid control. If some regular method as above outlined were adopted, we should hear no more of those distressing cases of *x*-ray burns, which are continuously cropping up.

Application to Disease.—It is not a little curious that the very diseases amenable in greater or less degree to radiation treatment are those hitherto least amenable to any treatment. Such are some forms and stages of sarcoma and carcinoma, lupus, tuberculous glands, eczema, psoriasis, cheloid, hypertricosis, acne, favus, herpes tonsurans, leukemia, amebic dysentery, alopecia areata, and chronic blepharitis.

Another most important field of usefulness, and one not as yet much touched upon, is the treatment of diseases of malnutrition, in which cases the radiation is used in its stimulatory quality, just as it may be used to make the hair grow rather than to cause it to fall out.

Space forbids the enumeration of the degree of usefulness of this treatment in the above named diseases.

Rodent Ulcer.—A victory, now securely scored for both the *x*-ray and radium, is the cure of facial cancer of the rodent ulcer type. Under favoring circumstances, this also may be accomplished by other means, but there are many cases which have already reached an inoperable stage and which are easily cured by the radiations. I exhibit such a case here tonight. The history of the case, briefly, is as follows:

Case I.—Mrs. E. M., aet. 57, referred to me by Drs. A. L. Mackin and David Webster, October 18, 1904. Patient first noticed, ten years ago, a pimple upon the cheek below the eye. This pimple continually grew larger, sometimes scaling over, sometimes raw, and developed eventually into an open ulcer, half an inch in diameter. The patient went through a great variety of treatments at the hands of different physicians, until finally, in September, 1901, she underwent an extensive operation by Dr. Lloyd of the Post-Graduate Hospital, and soon after malignant ulceration again appeared. Examination on October 18 showed the following: The upper third of the cheek, as can be seen now, is occupied by extensive cicatricial tissue, indicating the site both of operations and of caustics. On the outer side of the lower lid was a rapidly progressing, eroding, broken-down edge, on the inner side a hard, infiltrated, carcinomatous mass. The space between was occupied by an ulcer into which a probe would extend a considerable distance. The patient was immediately put upon

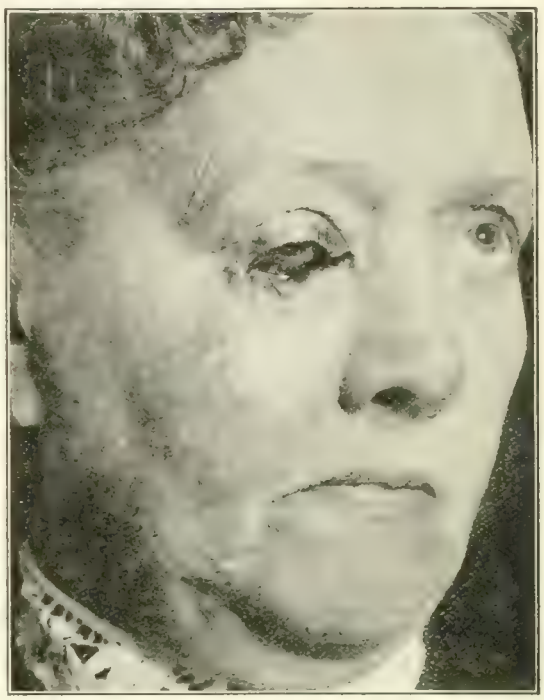

Fig. 1—Mrs. E. M.

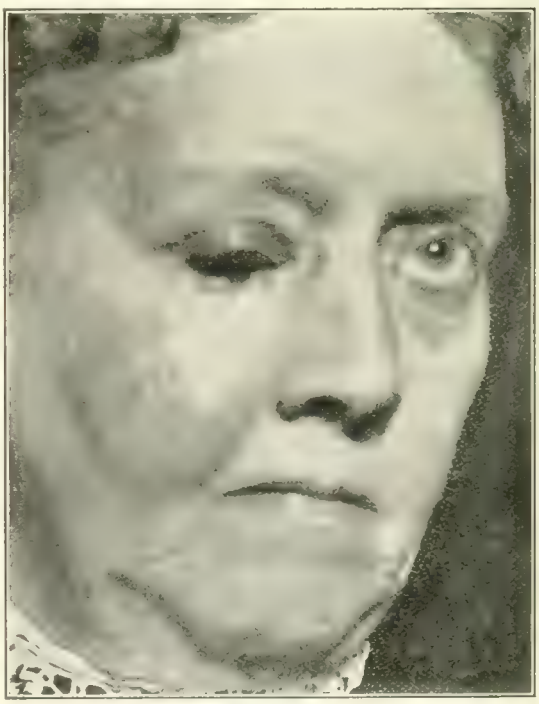

Fig. 2—Mrs. E. M.

fluorescin, six drops of an aqueous solution, one to thirty, three times a day, and *x*-ray treatment. The disease did well from the first moments. The pain was at once diminished, and in two months the ulcer was entirely healed. The accompanying illustrations (Figs. 1 and 2) from photographs exhibit

the general condition of affairs both before and after treatment.

This case illustrates particularly this point: If at the moment of complete cicatrization the *x*-ray had been pushed with vigor, the new and healthy tissue would itself quickly have broken down, and we should have been obliged to report a failure to cure.

Case II.—Mrs. J. J., aet. 52. Previous history unimportant. Patient was subject to attacks of eczema, and about eight years ago first noticed a very small "water blister" upon the temple. This persisted, although frequently appearing to heal, and has grown steadily and slowly ever since, until it appears as shown in Fig. 3. The tumor is 1¼ inches in diameter, and is raised up one-third of an inch. It is of a cauliflower-like appearance, is extremely vascular, and bleeds easily.

The report from the Pathological Department of the Post-Graduate Medical School and Hospital upon a specimen taken from the tumor was as follows: "Microscopic examination of the tissue from Mrs. J. J. shows the histologic structure of so-called rodent

Fig. 3—Mrs. J. J.

ulcer (superficial epithelioma). H. T. Brooks, November 4, 1903."

December 7: The tumor has steadily diminished from the first treatment. It has retracted from the edges inward, leaving a sound skin behind, and has flattened down daily. The size now about the diameter of the ring finger. It shows a disposition to concavity rather than convexity.

December 14: Mild *x*-ray dermatitis and heavy scab falling off.

January 30, 1904: The tumor was entirely cured, although the patient took some more treatments from mere solicitude as to the outcome. For results see Fig. 4. The cosmetic result is also perfect.

Case III.—W. H. H., aet. 60. July 20, 1903. The patient has upon the left cheek an induration or infiltration about 1¼ inches in diameter and superimposed upon this is a raised mass ¾ of an inch in diameter, elevated about ¼ of an inch above the surface. See Fig. 5.

July 31: The induration has entirely disappeared and the ulcer is elevated about 3-16 of an inch above the surface.

August 27: Malignant tumor is contracted in area, but stands out like a filbert attached by a broad pedicle. It is dry and scaly. No induration around it.

September 30: A contraction around the base of the tumor, which latter is bulb-shaped, placed on a stem or pedicle.

Fig. 4—Mrs. J. J.

December 2: Placed elastic ligature around the epithelial mass at base.

Fig. 5—W. H. H.

December 4: The seat of constriction inflamed and tumor ready to fall off. Microscopical examination shows nest cells characteristic of epithelioma.

Patient Cured. See Fig. 6.

Epithelioma involving the lymphatics and glands and deeper structures of the face, neck, tongue, and throat, cannot, as yet, in its well-established and late

stages, be cured by radiations. But seen and treated early, it can be cured. The same is true, no doubt, of surgical operation. But a danger of cutting is the setting free of cancer cells into the incised tissues and subsequent recurrence. This danger does not exist in the radiation treatment. Radiation, on the contrary, clears up the inflamed and involved lymphatics and glands and may cure an initial small and early focus of the disease.

The following case is reported in illustration of these statements. P. L. M., aet. 55, physician, seen April 19, 1904. He first noticed about six weeks ago a pain at the base of the tongue on the right side, and discovered an ulcer at that point. This was treated with nitrate of silver and again with nitric acid, but showed no disposition to heal. Examination reveals nearly at the base of the tongue on the right side a sharply excavated ulcer with well-defined linear elevated edges of the size of about the end of the finger, oblong in shape. The patient was at once put upon fluorescin solution as above described, and radium,

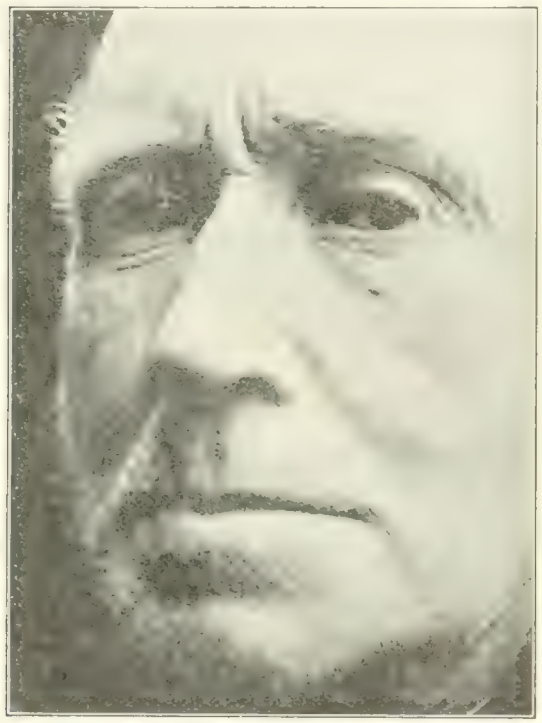

Fig. 6—W. H. H.

one million radioactivity, used about half an hour daily, and the *x*-ray.

May 26: Patient met a friend, a distinguished surgeon, who advised an immediate operation. I asked him to wait a while, which he did, though much disturbed by his friend's advice.

May 31: Ulcer reduced in dimensions to about the size of the end of a lead pencil; induration has disappeared. Owing to the patient's state of mind and my own responsibility in the matter, I took the patient to see Dr. W. T. Bull, who also advised immediate operation. I again asked the patient to wait, and he was willing to do so.

June 22: I took the patient to both surgeons, Dr. Bull and the patient's friend, and both reported that there was a complete resolution of the infiltrated area which they had both first observed, and that they saw no reason for operation, in the present condition of affairs. As a matter of fact, the ulcer was entirely cured. The patient returned home, and has had no trouble since.

Sarcoma.—Very many cases of large sarcomatous growths have been cured. Such cases have been reported by Coley (case of Dr. Fisk of Brooklyn) Skinner, Johnston (three cases) and others. On the other hand, innumerable other cases have not been cured. Why this difference? This answer cannot be given. We can only say that the law of control in these cases is unknown. There is ground for hope that it may yet be discovered.

Primary Carcinoma of the Breast.—I have had and published a very considerable number of cures to date of this condition. And also a large number of failures. An analysis of success and failure shows this, among other things: If the initial tumor is seen early and is small, a cure may occur even though the lymphatics are indurated and swollen glands exist in the axilla. The lymphatics and glands quickly become apparently normal, and the small tumor slowly disappears. But on the other hand, a certain type of flat, disk-shaped and not very large adenocarcinoma will go on growing in size and invasion in spite of the most persistent use of *x*-ray or of radium. Why? We do not know.

Or again a certain type of medullary or infiltrating tumor, *cancer foudroyante,* rapid cancer, will race on to general metastatic infection regardless of radiation treatment. This type cannot be arrested by radiation. I think most surgeons will also admit that operation would not in the same cases have saved the patient's life. Again, a large carcinoma (schirrus) will not notably diminish in size and disappear under radiation. What will happen is a great reduction in the softer, outer edges of the tumor, and its reduction to a harder and more clearly defined mass, and at the same time a disappearance of the cord-like lymphatic vessels and of enlarged glands. What, then, should be done in such cases? The tumor is now simply a foreign body. Radiation will not remove it. Obviously, it should be removed by surgical operation.

The situation, to my mind, seems to be about this: A cancer is a most dangerous foreign tenant, and should be cut out. But, and it is a very big but, the cutting out process carries with it another most dangerous feature, and that is the incision of lymphatics, and to say nothing of innumerable small infected glands, impossible in many cases to dissect out. On the other hand, radiation will not remove the tumor, but, and this is equally a very important but, it will clear up of cancer cells all the outlying territory right up to the tumor itself, and now an operation can be a comparatively safe one.

There can, in my mind, be but one deduction to derive from this situation. It is a plan I have long advocated, and one which I invariably follow. It is this: Practice *x* and radium radiations thoroughly, say six weeks to two months, *before* operation; and practice it as well *after* operation, say for about the same period of time. In this manner we avoid the Scylla of "soiling the wound" and the Charybdis of failure to remove the tumor. And by radiation treatment I do not mean a destructive effect, but I mean a radiation which just falls short of producing a mild dermatitis, or, to put it in another way, a radiation which just barely produces a mild dermatitis, in from four to six weeks. With this degree of radiation I have always found that the lymphatic vessels cease from being sensitive to the touch and cease to exhibit signs of inflammation. While the axillary glands may not in this period of time subside, it is probable that they do not hold active cancer cells.

But at this point one may remark, How do you know that outlying areas of cancer infection are neutralized of infection and that the seat of the disease is again localized as in its beginnings? I reply:

1. By the facts of the observed effect in many cases of recurrent cancer of the skin where this actual fact

may be visibly studied and may be verified by palpation. Nothing is more common in the history of radiation than to see large areas of skin-infected carcinoma clear up, leaving a healthy skin.

2. By the early cure of recurrent cancer in cicatrices.

3. By observation of the behavior of cancer of the mucous membrane where under radiation a distinct line of demarcation unfolds itself between the affected and the sound mucous membrane, and by that sign affords a new indication to the surgeon of where to incise.

4. By palpation of indurated lymphatic vessels in breast cancer. Take a concrete instance of this alone. What surgeon would prefer to cut through infiltrated lymphatics, when he could later on cut through flexible and disinfected lymphatics?

I will quote a single case to illustrate the return to an apparently normal condition of the region of tissue near the malignant growth, and to illustrate the fact that on the mucous membrane an absolutely clean line of demarcation may be established.

Patient, C. A. A., was referred to me by Dr. C. W. Buffum, with a detailed account of microscopical examination of sections made by Dr. Edw. K. Dunham of the Department of Pathology of the University and Bellevue Hospital Medical College. The case was only simply of classical epithelioma with characteristic microscopical and macroscopical appearances. It was partly ulcerating and partly solid infiltration. The disease occupied tthe posterior region of the tongue and involved the velum palati, and from this latter region a dark, dusky red extension of the disease passed over the roof of the mouth to the front teeth. In five days after beginning radiation, including three treatments only, I made the following note: "A serpentine line of demarcation appears on the mucous membrane of the hard palate, separating sharply the active disease from the sound tissue. The red, dusky inflammatory tissue ended sharply at this line and from it onward the mucous membrane had now assumed its light colored pink and healthy tone."

We will suppose that an operation had been determined upon before the *x*-radiation. It is obvious that there would be no guide as to a line of incision so far as the hard palate was concerned. Suppose again that operation was decided upon after the radiation. It is perfectly apparent that there would now exist a determining feature which would allow the surgeon to decide where to make his incisions. What occurs thus obviously under the eye, occurs also, as we know by the other evidence brought forward in other regions where the delimitating effect is not so plainly visible.

It may, however, be objected that the wound will not heal as well after radiation. Grant the full weight of this objection, and I should reply, better slow healing than a recurrence. But this objection is not a valid one. I have referred patients in a number of cases to surgeons for operation, and we have observed no delay in the healing processes.

But one surgeon has gone so far as to say that gangrene is more likely to occur if the patient has been *x*-rayed before operation, and cites two cases in his own experience. I was present at one of these operations, and saw the surgeons' and the assistants' fingers frequently soiled by the gangrenous material of a large open ulcer of the breast, which was in the course of excision, and as frequently immersed in the fresh dissection. In this case the subsequent occurrence of gangrene in the wound might well have been expected, to say the least.

Taking, then, in conclusion, a broad and conservative view of the present position of radiotherapy and of its relations to surgery, I believe that the best interests of the patient demand a combined treatment. An early operation is certainly the most important thing for the patient, but so also is an early *x*-ray treatment. The particular case which would have been curable by the operation, would also as likely have been cured by the radiation. In the latter event the operation will not prove to have been necessary. If the *x*-ray fails in a reasonable time, then the patient is in a better condition than before to submit to the inevitable operation. *In short, I believe that preoperative radiation should precede every operation for cancer with as much reason and force as preoperative aseptic or antiseptic cleansing of the skin to be incised.*

But, in reality, in cancer no hard and fast law can be laid down which shall apply to all cases, for the reason that each case is, in a sense, a law unto itself according to its degree of advancement, its location, and its nature. My plea is simply to avoid preconceived opinions, not to place operation and radiation at two opposing extremes facing each other belligerently, but rather gladly to avail ourselves of both, letting each method mutually help the other rather than to lose the aid of either. *"In medias res tutissimus ibis."*

In this brief glance at the possibilities and the shortcomings of radiotherapy, I have not referred to my own method of artificial fluorescence. I did not wish to cloud the issues. But in every case I have treated I have employed artificial fluorescence on a plan already fully published, and I attribute any success I may have had largely to this method.

1. Radiation treatment exerts a retarding effect upon the growth of some cancers.

2. It cures some cases—the ratio to operative measures is not here discussed.

3. Preoperative radiation will increase the ratio of cures by operation.

4. Preoperative radiation transforms some inoperable cases into operable cases.

5. Preoperative radiation is recommended as a precautionary measure, probably quite as important as preoperative antiseptic preparation for surgical operation.

BILE-TRACT ADHESIONS.*

By ROBERT T. MORRIS, M.D.,

NEW YORK.

PROFESSOR OF SURGERY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE new subject of bile-tract adhesions is destined to awaken the medical profession as we were awakened by the subject of appendicitis. Surgeons have often operated for the purpose of removing gallstones, and have found to their discomfiture that no gallstone was contained in the cavity of the gallbladder. Adhesions were separated incidentally, and an explanation was given to the effect that the concretion or concretions must have passed on before the operation. Patients recovered from their symptoms, and the explanation seemed to have been a good one. It was usually wrong.

Patients with dilatation of the stomach, or with chronic gastroduodenitis, or mucous colic, or intestinal dyspepsia, or gastric dyspepsia, or gastric neuralgia, or chronic constipation, have often been the subjects of unsatisfactory consultation by expert diagnosticians, in cases in which a ready explanation for the symptoms lay close at hand, in the presence of the adhesions. Byron Robinson called attention to the fact that peritoneal adhesions were

* A paper read at the meeting of the Bridgeport Medical Association, for February, 1905.

found in the vicinity of the bile-tract more frequently than elsewhere in the peritoneal cavity aside from the pelvis, but he did not comment much upon the observation. Men engaged in post-mortem work have noted that it was often difficult to find the foramen of Winslow, because adhesions were in the way. They have observed that the gall-bladder and common bile-duct were adherent to surrounding structures more or less, in a rather large proportion of all of their post-mortem examinations, but little significance was attached to such findings.

Now let us all think about the matter for a while. Subacute cholecystitis is very common. It is sometimes called stomachache, sometimes gastroduodenitis, and sometimes by as many other names as we used to give to appendicitis, before the classical paper of Fitz appeared. Subacute cholecystitis when called improper names strikes back, just as appendicitis used to strike back under the same circumstances. Catarrh of the bile-tract was commonly thought to represent an extension of infection from the bowel, until Lartigau showed us that the colon bacillus was carried to the liver from the bowel by the afferent vessels of the portal system. The colon bacillus, arriving from behind in this way, seems to be the chief malefactor in catarrhs of the bile-tract, in temperate climates. The toxins of the colon bacillus, and of its terminal infections, apparently do not often penetrate the bowel wall in a way to do serious damage to endothelium, excepting at the site of the appendix, and of the bile-tract. In the appendix region they can damage the peritoneum when swelling of the inner coats of the appendix in their inelastic outer coat leads to compression anemia of the inner coats, and leaves the latter disabled against attacks of bacteria. In the bile-tract the toxins probably penetrate all of the thin walled structures in such a way as to cause desquamation of endothelium on the peritoneal side. When desquamation of endothelium occurs, plastic lymph is thrown out, and the resulting adhesions produce various degrees of disturbance. Adhesions between the gall-bladder and the liver are perhaps the least harmful. Adhesions between the cystic duct and the adjacent peritoneum of other structures can cause angulation of the cystic duct, and give rise to symptoms that are mistaken for gallstone colic, or colic from the passage of inspissated bile. Adhesions between the bile-tract and the pylorus can inhibit peristalsis and cause constipation, chronic dyspepsia, and dilatation of the stomach. Adhesions between the bile-tract and the hepatic flexure of the colon can cause constipation and perhaps mucous colic, but I believe the latter to represent a functional neurosis. It is not a diagnostic entity, but is apparently a symptom like a cough or a sneeze, and due to reflex from a peripheral irritation. This peripheral irritation I believe to be due, in bile-tract adhesion cases, to the pulling of adhesions upon the peritoneum in the sensitive area of the semilunar ganglia. Very extensive functional disturbance of abdominal viscera is caused by these webs of adhesion, like spider webs, that extend from the bile-tract to neighboring viscera, and that pull upon the great sympathetic ganglia. The number of symptoms that we are relieving by clearing away the work of the gall-spiders, is a constant source of interest. Thousands of patients who are now suffering from gall-spiders, are to be relieved by surgeons during the next decade. There is probably no physician in the world engaged in general practice, who has not a number of such patients under his care to-day, but none of us have been equipped for a diagnosis until very recently. In medicine and in surgery, we can find almost anything that we are looking for. We have not been looking for the immediate and remote work of the gall-spiders, any more than we looked for the immediate and remote disturbances caused by the infected appendix previous to 1886. There is no literature that I am familiar with on the subject of gall-spiders. It is coming. The literature of the next decade will be alive with interest in this subject. We all knew of the prevalence of peritoneal adhesions in the region of the bile-tract, but we overlooked their significance.

Perhaps there are many patients with bile-tract adhesions who do not suffer any discomfort. That is not for us to say just yet, for we do not know. We do know that the viscera involved in such adhesions were intended by nature to be particularly free, and when they are suspended by adhesions instead of by the natural peritoneal supports, it is fair to assume that nature beckons to the surgeon to come to her relief in almost every case. Such a patient may have been an invalid for years, and yet not have reported anything to go with the post-mortem findings. At what age do bile-tract adhesions form? At any age, but perhaps most often in childhood, when the delicate tissues are least resisting. Desquamation of eipthelium of mucosa of the bile-tract, with deposit of cholesterin and formation of gallstones, is most apt to occur after middle life; but desquamation of the endothelium of adjacent peritoneum seems to occur frequently enough in the very young, as well as in the aged, and probably because of the thin walls of the gall-bladder and the bile-ducts. How are we to make a diagnosis of gall-spiders? We are to go over the tailings from the ore mill in which we previously found gastroduodenitis, diaphragmatic pleurisy, acute cholecystitis, acute indigestion, and a group of cases without very definite diagnosis in which there was a history of epigastric tenderness, rigors, febrile reaction, and general malaise lasting for a few days at a time. In going over these cases months or years after the acute symptoms have disappeared we are to note if there is undue tenderness on pressure over the bile-tract. A tenderness that is pretty persistent. It may be absent on some days, but present to a greater or lesser degree most of the time. The patient will complain of a certain degree of discomfort in the bile-tract region, and at times when he is most disturbed the abdominal muscles will become rigid in order to splint the disturbed peritoneum. Having found these characteristic signs of bile-tract adhesions, we are to exclude other causes for the same symptoms; and that requires diagnostic acumen, and high-class consultation.

In several cases which were sent in for gallstone operations, the diagnosis of bile-tract adhesions without the presence of gallstones was made in advance of operation, on the fact that the colic was less severe and more transitory than it is apt to be when the muscularis of the gall-bladder or bile ducts is trying to force out a concretion. In a number of other cases the patient, before operation, was found to be suffering from the influence of a loose kidney, rather than from bile-tract adhesions or from gallstones, although both conditions can occur simultaneously easily enough. The same statement applies to cases of enteroptosis. In all of the cases that were actually subjected to operation for the purpose of separating bile-tract adhesions, however, such adhesions were always found to be present. What is the treatment for gall-spiders?

Separate the webs of adhesion and prevent their recurrence by applying one or two satisfactory resources. The best resource, I think, consists in

spreading a sheet of chromicized Cargile membrane over the roughened points of peritoneum, and leaving the membrane to present a mechanical obstacle to re-adhesion at such points. The other resource consists in sprinkling aristol over roughened points of peritoneum, and waiting for the aristol to form a protecting lymph coagulum before the abdomen is closed.

Musser is the first physician to take a radical position, and to say that the gall-bladder should be removed in cases of infective cholecystitis, because of the danger of repeated excursions of infection from this focus. His stand is probably as important in the way of progress as was the stand of McBurney in advocating early removal of the infected appendix. The gall-bladder seems to be of as little consequence as other rudimentary organs, excepting in the way of making trouble. Many animals have no gall-bladder, notably the cervidæ. Patients with occlusion of the gall-bladder, due to irritation from calculi, and patients who have been deprived of the gall-bladder by operation, show no results pointing to the idea that the viscus was ever of any value to them. Removal of the gall-bladder with the steps in technic of suturing a drainage tube in the cystic duct, and of preparing Morison's pouch properly, is a very safe operation.

In my earlier operations for separation of bile-tract adhesions, the gall-bladder was left intact, but it is now removed. In one patient, Mr. W. T. R., in whom the gall-bladder was left intact, a subsequent operation by Dr. Hartley, showed no recurrence of the dense adhesions between the gall-bladder and pylorus, over the area that had been protected by Cargile membrane, but new adhesions had formed posteriorly. This would seem to indicate that re-infection can occur at any point in the bile-tract area.

As a rule, the operation for relieving the patient of bile-tract adhesions, is almost startling in its success, and patients hardly an hour out of anesthesia will sometimes say that they are more comfortable at that moment than they had been for months or years previously; but one feels the need for being extremely careful in making a good diagnosis in order to avoid the chagrin that comes to a surgeon when he suspects that he has done a needless operation. Surgeons do not speak of this chagrin, because they are accustomed to withstanding shocks, but if there is any one feeling deep down below all others in any surgeon's mind, it is the fear that he may do something needless. Personally, I have not, as yet, made a mistake in diagnosis in gall-spider cases, but stand in dread of it, nevertheless, and perhaps have allowed a good many patients to go uncared for because of reasonable doubt about adhesions being the dominant factor in any given case. Our tendency will be at first to do too little of this work, than to do too much, and finally to put the matter on the scientific basis where appendicitis now stands.

One cannot look over an average audience at the theater without seeing at least fifty people who are suffering from some degree of disturbance caused by bile-tract adhesions; so there is a vista of unknown horizon newly opened up for us. Adhesions in the pelvis belong to old history, well understood. Adhesions in the cecal region belong to new history, but thoroughly understood. Adhesions standing in abundance midway between those of the pelvis and those of the cecal region, furnish history that is yet to be written.

616 Madison Avenue.

INTRATRACHEAL INJECTIONS.*

By J. W. GLEITSMANN, M.D.,

NEW YORK.

When I selected a subject for this evening's discourse, which, apparently, belongs to the domain of the specialist and seems to be of less interest to an assembly of general practitioners, I was influenced to do so principally by a request of your President. But the topic is not one which requires special knowledge or experience, and everybody who is familiar with the use of the laryngeal mirror, which I deem essential for a successful execution, will soon learn to make the applications properly. Besides, their value as a curative agent in many cases, as an ameliorating factor in others, cannot be denied, and their harmlessness as well as their efficacy have been attested to by numerous writers.

From what I know from the literature, from programmes of medical societies, and from personal intercourse with colleagues, intratracheal and intrabronchial medication does not enjoy a great popularity nor widespread usage, although in the last few years the number of publications have considerably increased. When I searched somewhat hurriedly the literature in Semons Internationale Centralblatt from its beginning in 1884 to the year 1903, which gives a very complete enumeration of all papers pertaining to laryngology and allied branches, I found only quotations of 41 articles referring to intratracheal injections, in addition to which there are several in other journals. This small number covering a period of 19 years, is quite out of proportion to the multitude of papers appearing on subjects of minor importance.

The history of our subject dates back to prelaryngoscopic times, and as it is quoted in numerous publications, I can be brief. Leaving out of consideration previous applications to the larynx proper, Horace Green[1] of New York, was the first to make applications to the trachea, and he read his first paper on the subject before the Medical and Surgical Society of New York, 1841, reporting several cases cured by his proceedings. Although unfavorably commented upon by the profession, he did not desist in his efforts, treated over 100 patients with various success, and had the satisfaction to demonstrate later before the New York Academy of Medicine the appearance of a probang in the tracheal wound of a man having attempted suicide, thereby refuting Trousseau's contention that it would be impossible to introduce instruments below the cords. He was soon followed by the English physician Alison,[2] who also speaks very favorably of these applications and their beneficial results, having himself already applied olive oil with a sponge to larynx and trachea, relieving the sense of tightness and dryness of these parts. Of the earlier writers may yet be mentioned Bennett[3] of Edinburgh, who, after communicating with Green, treated bronchitis with asthma and claimed a decided effect in lessening the cough and delaying asthmatic paroxysms.

Later investigators broached the subject from a physiological standpoint in two directions, viz., as to the tolerance of the trachea to different drugs and as to the capability of its mucous membrane of absorbing the solutions. Bergeron[4] was amongst the first who injected medicated liquids in the trachea of cows, horses, and dogs and found them borne without trouble. He also gave relief to a phthisical patient by 25 calming injections in as many days. He, as well as his followers, injected the liquids with

*Read by invitation before the East Side Physicians' Association, January 20, 1905.

a hypodermic syringe through the skin into the trachea. Brancaccio[5] injected 15 to 20 grammes of blood in this manner into the trachea of dogs, drop by drop, and with a continuous stream, and noticed no cough, no dyspepsia, no evil sequelæ. Penhale[6] used injections of turpentine, carbolic acid and chloroform successfully in calves suffering from parasites in the trachea and bronchi. Schmalz[7] of the Berlin veterinary school made numerous injections in horses for therapeutic purposes and found that the respiratory mucous membrane of the horse possesses a high degree of absorbing power, that the animals are very little molested and that large quantities can be repeatedly injected. He treated catarrhal conditions of the nose and throat and relieved the obstinate, dry laryngeal catarrh with solutions of ½ per cent. alum and 1 per cent. salt. The best results he had in hemophilia of the horse, which resisted all other remedies, but was cured by repeated injections of 10 to 20 grammes of a solution of iodine 1 part, iodide potassium 5 parts to 100.

Botey[8] of Barcelona repeated these experiments on hares and finally had the courage of his conviction to make injections to himself. He relates an instance, when, in an old horse assigned for the purpose, almost 32 liters of water were injected before it died. Of his experiments the most interesting is that by which he tested the comparative tolerance of the tracheal and esophageal tract by injecting a solution of ½ per cent. bichromate of potash into the trachea of one and into the esophagus of another hare, killing both two days later. The first animal showed no ill effect, and at the autopsy the respiratory mucous membranes were normal without hyperemia. The other animal lost its appetite, crouched down in his cage, and, when killed, the stomach showed congestion and inflammation. Being accustomed to inspect and touch the interior of his larynx, Botey made injections himself into his trachea, beginning with 10, then 25, lastly 50 grammes of distilled water, followed by no symptoms whatever, except a slight lowering of the number of his respirations and pulse. He made use of his experience in a case of laryngeal and tracheal syphillis, in which mercurial treatment had failed, and cured the patient by seventeen injections of iodide of potassium and a small quantity of bichloride of mercury.

From this time dates the usage of intratracheal injections for therapeutic purposes, although Rosenberg[9] employed in 1886 intralaryngeal injections of menthol oil for laryngeal tuberculosis, and considers their effect anesthetizing, analgetic, and antiparasitic. I found the first references in the English literature, when Downie[10] read a paper before the Glasgow Medical Society (1889), in which he states to have treated pulmonary and laryngeal phthisis, bronchiectasis and pulmonary gangrene. In the discussion following several colleagues took part, who were inclined to accept a favorable influence on the symptoms, but were skeptical as to their lasting benefits. In his later paper[11] he adds a number of diseases amenable to injections, cites satisfactory cases, and claims that, with practice, injections, of which he uses only thirty drops but two to three times, he could dispense with the laryngeal mirror. We see from his report that already at this early period the drugs and combinations employed were practically the same as we administer at the present time. T. Grainger Stewart,[12] to whom subsequent writers frequently refer, cured an advanced case of fetid bronchiectasis with a solution adopted by his followers, viz., 2 per cent. guaiacol, 10 per cent. menthol, 88 per cent. olive oil, the patient increasing in weight 20 lbs. Of English authors may yet be mentioned Sharpe,[13] who gave a drawing of a fairly good syringe, under the name of Beehag's syringe; Campbell,[14] who treated tuberculosis and a variety of diseases, and found excellent results in three cases of hemoptysis, with immediate cessation of the bleeding; Bronner,[15] who adds salol and europheen to the list of remedies, and recommends the injections also in tuberculosis and the chronic laryngotracheitis prevalent in the North of England; finally, Thomas,[16] who investigated the effect of the injections as to possible pulmonary congestion and hemorrhage. He used them in pertussis, emphysema, asthma, acute, chronic, fetid bronchitis, bronchiectasis, and phthisis, in which in the first stages the results were very favorable.

I shall not tax your patience with an exhaustive literary review, but confine myself to two foreign and the principal American writers. Mendel of Paris, who supplemented his first communication[17] by an exhaustive paper, four years later[18] (1899) applied either bromoform or iodoform, or guaiacol or menthol in tuberculous patients, and observed cessation of cough and expectoration, return of sleep and appetite, increase of weight and drying up of cavities. Thorpe[19] of the naval station at Wei Hai Wei found the injection a valuable adjuvant to the open-air treatment of his patients, saw bacilli disappear and the patients gain weight. He succeeded without aid of the laryngeal mirror.

In the United States, Dr. Coakley of New York made most interesting experiments at the Loomis Laboratory, showing how quick absorption takes place in the trachea. Injecting a solution of India ink into the trachea of rabbits and killing them two hours or sooner afterwards, no pigment was found in the trachea nor bronchi, and only traces in small lymph-ducts. Early in January, 1896, Muir[20] of this city read a paper before a medical society giving his experience of the method during a trial of three years in forty patients, the majority suffering from tuberculosis. He prefers by far the alleviating, resolving effect of the injections to internal administration of opiates, speaks of the favorable influence they have on the secretions of the diseased area, and dwells upon the ready absorption of the liquid by the mucous membranes. Very soon afterwards Barton[21] published an excellent paper, coinciding with Muir's views, and found as advantages of the injections the direct application to the irritated mucous membranes, the immediate relief of the most distressing symptoms, the antiseptic effect in febrile cases, the rapid absorption, and the avoidance of disturbing the stomach and digestion. Thompson[22] of Cincinnati, who wrote me in Janaury of the present year that he had been using intratracheal injections during the last twelve years, observed rapid and prolonged general effect f. i. anesthesia with menthol injections, and, in addition to a variety of diseases, advocates them in chronic catarrhal inflammation of the mucous membrane of the trachea. He insists on the introduction of the syringe between and below the cords. Murray[23] and Anderson[24] made injections with satisfaction in tuberculosis, and the latter in several publications considers them of the greatest usefulness in secondary affections of tuberculosis, as bronchitis, pneumonic extension. He also used ichthyol (2 per cent.) with menthol-camphor (5 per cent.), which, although lessening the secretions, he finds less agreeable to the patient. Donellan,[25] in his articles, relates his experience in asthma, bronchorrhea, chronic catarrhal cough, and fetid bronchitis, and reports several cases. He also advised a very suitable syringe, with lateral perforations. The latest paper I could lay hand on is by Hubbard,[26] read before the American Laryngol. Association (1904), and kindly sent to me by the

author as manuscript, the Transactions having appeared only a few days ago. Although he does not deny the utility of injections in alleviating the distressing cough and irritation in tuberculosis, he is more reserved as to their limitations and ultimate effect. He, as well as most writers, is adverse to their use in the acute stage of any type of inflammation, and says that the injections are not given for the purpose of systemic medication, and that they take the place of so-called stimulating expectorants, the treatment being essentially local, and absorption not the object.

These somewhat extended abstracts give us not only the historical development of the method and the views of the principal writers, but embrace also to the greater part the indications and remedies employed, and serve to prove the propriety and efficiency of intratracheal injections. I therefore do not need to enter at length into the different features, and can summarize more briefly.

The experiments on animals, as well as the injections to the human beings, attest to their harmlessness, and I have not been able to find a single reference where an unpleasant or serious effect has been reported. It is necessary to make this assertion, as the lower respiratory tract is *a priori* not intended for medication, and some physicians deprecate the idea of injecting liquids into the trachea.

Although necessarily the number of diseases to be treated, as well as the choice of remedies, is limited, the advantage of applying the latter directly to the seat of the lesion is obvious, and instances are frequently related in which the injections showed their beneficial effect when other treatment had been futile.

Having frequently referred to the absorptive power of the tracheal mucous membranes, shown in the foregoing by the experiments of writers on animals themselves, and on patients, I cannot fully subscribe to Hubbard's view as being an irrelevant factor. If a moderate dose of a non-irritant remedy is properly injected, very little, if any, is coughed up, and consequently must become absorbed in the trachea. If we add to our vehicle menthol, recommended by Rosenberg years ago for tuberculous laryngitis, or iodoform or guaiacol, the latter being to the present day a favorite for tuberculosis, and if the larger part of the solution remains in the trachea, I do not see why we could not expect at least the same effect as by giving the drug by other channels.

The antiseptic effect has already been mentioned by Barton, also the advantage of not disturbing the digestion, so often a vital point in a run-down individual.

If we are not carried too far by enthusiasm, as some writers are, and limit the field of injections to their proper indications, we will not have to regret their adoption in suitable cases. However much may have been written about their effect in pulmonary tuberculosis, I am not inclined to believe in a cure by them *per se*. They are certainly useful in alleviating the dry cough in the beginning stage by promoting the secretive power of the mucous membranes; they may at a later stage modify favorably the putrid secretions: but I, for my part, see a cure of tuberculosis aside from climatic treatment only from an unlimited use of pure air, liberal diet and specific medication, of which I have a number of cured cases on my record. In the quotations from the literature all the diseases were mentioned in which injections had been used, and I can therefore recapitulate briefly. For bronchiectasis and blennorrhea I know of no better treatment, and the injections act almost as a specific. Many, but, in my experience, not all, cases of asthma will be relieved; the distressing dyspnea and the whizzing râles decrease or cease altogether when the injection has loosened the viscous secretions and assisted in their expectoration. But we cannot speak of a cure of asthma proper as long as we cannot eliminate the underlying causative factor. I concur with Dr. Hubbard in not recommending injections for acute tracheitis, but found them most efficient in the different varieties of chronic tracheitis and bronchitis, and treated a number of patients with decided success. Cases of obstinate tracheal syphilis have been cured and the fetid pulmonary gangrene has been favorably influenced. I have no personal experience as to their usage in pertussis and hemorrhage, but although Campbell reports immediate cessation of bleeding after injections, I would, for my part, hesitate to make them in the latter instance, as irritation of the trachea and subsequent coughing cannot always be avoided, and therefore the risk of increasing the hemorrhage has to be considered.

We read in the later publications no more of astringent or caustic solutions as were applied at an early period. If we use them nowadays it is with the intention to produce a topical, localized effect, for instance, to an ulcer or tumor, and we make them with sounds or cotton-carriers of proper curve to a well-defined locality. The diseases for which intratracheal injections are recommended are deeper seated, spread over a larger area, and require larger quantities, therefore solutions of a non-irritant character. The general consensus is to use as vehicle for injections bland, purified oil, and if this requirement is complied with, it matters little which preparation we use. All writers agree to the efficacy and beneficial influence of menthol, which, according to the disease and the predilection of the practitioner, can be added in proportion of 1 to 15 per cent., although the latter figure is higher than I employ. The next favorite is guaiacol and creosote carbonate, both excellent adjuvants in tuberculosis, from 1 to 2 per cent., the latter also highly recommended to relieve bad odor from cavities, bronchiectasis, gangrene. Chlorophenol, 1 per cent., europheen, 1 to 2 per cent., are also well spoken of for similar affections. Bromoform, iodoform, turpentine, salol are less frequently used, and of remedies seldom employed, except by their advocates, I will only mention calomel, 1 per cent., of which one author speaks favorably.

For my part, I have always used as vehicle the hydrocarbon oil, sold under the name of benzoinol, which, besides its purity, has the advantage of being furnished in different combinations, of which the addition of menthol, 1 per cent., is the most useful one, and very much appreciated by patients. If desired, more menthol can easily be added, but I have found 5 per cent. sufficient for all purposes. I have also used the oil with ½ per cent. menthol and camphor each, but often found the latter too irritating. I need not say that I employ also the other agents in suitable cases, but I find the list of remedies limited, and transgressions of little avail or benefit. I once tried to decrease the copious secretions of a case of bronchiectasis by an addition of tannic acid, but failed to make any impression, except to excite the disgust of the patient.

As far as the applications themselves are concerned, I stated already at the beginning that I consider the use of the laryngeal mirror indispensable. It may be that some gentlemen possess the skill to introduce the distal end of the cannula be-

tween and below the cords without aid of the mirror, but to be sure that the cannula is in its proper place, I feel the need of the mirror. It is possible to inject some liquid without it into the larynx, which, at a deep inspiration, will allow a certain quantity to pass betweeen the open cords. But if a full injection is to be given, the glottis will close rapidly at the entrance of the liquid, and to be effective, several such injections are necessary. I prefer to give only one injection of the desired quantity, from four to eight drachms each time. A few whiffs of a weak cocaine spray will materially facilitate the introduction of the cannula below the cords.

A number of syringes have been devised by different authors, of which I show you the syringes of Dr. Muir and Dr. Donellan. Both have metal cannulas, and especially the latter serves its purpose admirably. But I found that in some cases the stiff, unyielding cannula gave discomfort to the patient and interfered with the delicate sense of touch which we must preserve when intending to introduce the cannula well down into the trachea. I had, therefore, cannulas made of hard rubber, which are stiff enough for successful introduction, but create no unpleasant sensation when coming in contact with any part of the larynx or trachea. When we wish to reach the lower part of the trachea, a different curve is necessary, and it is best to have several cannulas, although by gently heating we can impart to the hard rubber cannula any curve we desire. The syringe itself is the well-known Hartmann ear syringe, holding one ounce, which quantity, in my opinion, ought not to be exceeded if we wish to avoid loss of solution by coughing or respiratory interference. Some patients do not cough at all after injections, but a moderate cough is not to be objected to, as it spreads the liquid into the bronchial ramifications. Sometimes at the commencement, and especially when patients are nervous and have an irritable throat, I use the small laryngeal syringe, called Hartwell's syringe, containing only a drachm, with which I can pass the cords and make the patients accustomed to the instrument and to the sensation of solutions in the trachea.

THE PRESENT STATUS OF BLOOD EXAMINATION IN SURGICAL DIAGNOSIS.*

By FREDERIC E. SONDERN, M.D.,
NEW YORK.

When Hematology emerged from its theoretical state into a science of practical utility to the clinician, the surgeon amongst others looked to it for aids in diagnosis and prognosis, and it is to the evolution of these and to the present status of their utility that I invite your attention. The most important sphere in which the examination of the blood promised aid to the surgeon, was as a guide to the existence and severity of an inflammatory process and to the presence or absence of a purulent exudate.

Since the beginning the number of leucocytes in a given quantity of blood has been looked to for this purpose, and many observers have carefully tabulated their leucocyte counts with the view of determining the degree of leucocytosis which indicates inflammation without exudate or with serous non-infectious exudate, that at which a purulent exudate may be expected, and finally that which would indicate a degree of systemic poisoning which would make any operative interference a hazardous procedure.

Twelve years ago, Sadler[1] claimed that leucocytosis was generally, though not invariably present in diseases attended with exudate of any kind, excepting in tuberculosis. Two years later Cabot[2] wrote an article calling attention to the significance of leucocytosis in suppurative conditions, having noted it in all cases in which pus was present, excepting two. He did not give the details of the counts at that time, and the article contains inferences now obsolete. A number of articles written during the next five years, deal more or less extensively with the subject of leucocytosis in suppurative conditions, but no actual figures are quoted, nor are the cited details pertinent to-day.

In 1899, Gries[3] stated that the relations of a leucocytosis to pus formation, when a normal or abnormal temperature is present, are equally interesting. He adds that a leucocytosis of 10,000 or more, in a woman in pelvic pain, after all acute symptoms have subsided, and eliminating diseased conditions elsewhere, is indicative of suppuration of some one of the pelvic organs.

Bloodgood,[4] in his article on blood examinations as an aid to surgical diagnosis, calls attention to the grave significance of a sudden drop in the leucocytosis in some cases, and in appendicitis advocates operation if within the first forty-eight hours the leucocyte count reaches 20,000.

Joy and Wright,[5] in an article on leucocytosis as a point of prognosis in appendicitis, conclude that the leucocyte count is a valuable aid to prognosis, and distinct from its diagnostic value. A high stationary or an increasing count indicates a morbid condition of increasing severity, which demands operation, no matter what the clinical symptoms may be. A low stationary or a decreasing count indicates that the severity is abating. Cases in which a falling count is accompanied by unmistakable signs of a bad condition form a rare exception, and the significance is obvious. No arbitrary set of values can be constructed, and a scheme should be followed in which one learns to have confidence.

At this point I wish to direct attention to some features concerning these older observations. That a leucocytosis was not invariably found in the suppurative lesions, and the comparatively slight leucocytosis which was believed to indicate the presence

*Read before the Surgical Section of the Academy of Medicine, New York, February 3, 1905.

of pus; both of these points at this stage giving rise to doubt as to the value of the procedure to the surgeon.

The paper by John B. Deaver[6] is an illustration of numerous publications of this kind, which have appeared during the last few years. His opening words are essentially as follows: "In the last few years there has crept into the profession the tendency to replace the bedside by the laboratory as a point from which to make a diagnosis; to substitute the highly magnified, but extremely limited field of the microscope for the broader view of the eye of the physician. This we regret, for in the majority of instances, the diagnosis must be made at the bedside without the aid of the microscopist, and any man who has no confidence in diagnosis made without the aid of the laboratory, limits his usefulness."

In the light of present knowledge, this seems a one-sided view, for I believe the truly conscientious man demands every possible aid available which may be of practical value, though he cannot be expected to use methods of questionable utility. The use of laboratory aids when at hand by no means lessens confidence in clinical methods, and is more apt to enhance the skill of diagnostician than to "limit his usefulness."

These adverse opinions as stated are chiefly based on the two points which I have emphasized; the absence of a leucocytosis in some cases in which pus is present, and inferring the presence of pus from a comparatively low degree of leucocytosis.

That there may be no increase in the number of leucocytes when a purulent exudate exists, was noted from the beginning, and this feature has been the greatest obstacle to progress, as it has discouraged observation. Leucocytosis is largely dependent on body resistance toward infection, and therefore the degree of increase can be no guide to the intensity of the pathological process. Good resistance will produce pronounced leucocytosis even in slight infections, and poor resistance but little leucocytosis in slight infections and possibly none at all in grave infections. No adequate clinical method exists by which this body resistance can be determined with sufficient accuracy to apply it as a factor to the leucocyte count, and this is the key to the disappointments encountered by the surgeon in utilizing these counts in diagnosis. It is also the reason why arbitrary leucocyte count standards indicating definite degrees of lesion cannot be fixed, and the statements indicating the significance of particular counts are, and must remain, subject to doubt.

Scarcely five years ago a leucocytosis of 10,000 under circumstances was looked upon by some as indicating the presence of pus, as I have stated, while since then the literature shows that the figure has steadily advanced. Cazin and Gros[7] state that 20,000 to 22,000 if at all stationary or if advancing to 25,000 indicates pus. This statement is followed by a number of German observers, who claim that a count of at least 25,000 is necessary before pus may be suspected. The last statement I have read is that of French,[8] who demands the presence of 35,000 before pus may be suspected, though pus is often present with much lower counts.

As a direct result of many blood examinations made in surgical diseases, I have been impressed during the last few years by the fact that the quantitative relation or differential count of leucocytes offers a far better guide to the status of an inflammatory process, and one which is not influenced to a perceptible degree by body resistance. Furthermore, that the leucocytosis present with a given differential count is a direct indicator of body resistance, which may also be of great clinical value.

I hesitated long before bringing these observations to your attention, but I am now prompted to lay them before you, owing to the rapidly increasing number of instances in which the blood picture looked at in this way, has successfully indicated the necessity for surgical interference, when the clinical manifestations were not so pronounced, and the leucocyte counts often misleading.

As it is my intention to remain on the practical side of this question, I will not burden you with a detailed consideration of the different varieties of leucocytes, their origin, or their specific use in the economy, especially as there are still many disputed points. Personal work with about 5,000 blood specimens carefully tabulated, gives me the following figures for healthy adults of the upper and middle classes of society of this city, and but few hospital patients. Leucocytes in 1 c.mm. of blood from 5,200 to 9,600, the average being 6,700. These figures were determined by use of Thoma-Zeiss chamber, almost invariable dilution 1:100 and actual count of corpuscles in 0.1 c.mm. of blood in most instances.

The same tables show a normal differential count of leucocytes to be as follows:

Leucocytes.	PERCENTAGES.			Actual number in 1 c.mm. [illegible] leucocyte count of 6,700.
	Low.	High.	Average.	
Small Lymphocytes	[illegible]	[illegible]	28.0	[illegible]
Large Lymphocytes	[illegible]	[illegible]	7.5	[illegible]
Polynuclear Neutrophiles	[illegible]	[illegible]	[illegible]	4,154
Eosinophiles	[illegible]	[illegible]	[illegible]	[illegible]
Basophiles	None	[illegible]	[illegible]	[illegible]

These figures are based on percentages obtained from actual count of at least 500 corpuscles in the center and not on the margin of the blood smear.

The particular point in question is the relative percentage of polynuclear neutrophiles, the determination of which is neither difficult nor tedious, particularly in the cases in question. While it is true that the percentage of these cells varies somewhat in health, as I have shown, and probably in the different states of body resistance, still these fluctuations are within fairly narrow limits. An analysis of 1,415 blood examinations, which I have made in surgical cases, shows three distinct blood pictures in inflammatory lesions, as follows:

First.—A relative percentage of polynuclear cells below 70, with an inflammatory leucocytosis of any degree, excludes the presence of gangrene or pus, at the time the blood examination is made, and usually indicates good body resistance toward infection. Of the large number of instances in my records, I will briefly mention but two, which will illustrate the point.

No. 12,971.—A robust young woman. Red cells 4,900,000. Hemoglobin 82 per cent. (v. Fleischl). Serous otitis media, and owing to extreme pain, condition of pulse, etc., suspected acute mastoid disease. Leucocyte count 28,400. Polynuclear cells 59.7 per cent. Clinical picture and leucocytosis would have indicated immediate operation, but the normal polynuclear percentage led the aurist to wait, and a prompt recovery without purulent exudate made operation unnecessary.

No. 13,610.—A boy convalescing from severe attack of an acute infectious disease, presented a clinical picture of acute appendicitis and a leucocytosis of 25,100. While surgical interference seemed urgently indicated, the general condition made it a risk not to be incurred unless imperative. The polynuclear percentage of 63.5 induced the attending physician to wait, and while he spent anxious days

in which the clinical signs and blood picture remained stationary, resolution without pus or gangrene resulted, and the child was saved an operation at a time when he was in very poor condition to stand it.

Second.—An increased relative percentage of polynuclear cells, with little or no inflammatory leucocytosis, is still an absolute indication of the inflammatory process, and the percentage is a direct guide to the severity of the infection. As above stated, in all the cases of which I have clinical record, no pus or gangrene was ever observed with a polynuclear percentage below 70. In children, where the polynuclear percentage is normally lower than in adults, I have seen pus or gangrene with the percentage as low as 73. In adults, a purulent exudate or a gangrenous process is decidedly uncommon with less than 80 per cent. of polynuclear cells, and the probability of their presence increases with the percentage. Eighty-five per cent. or over of polynuclear cells I have never seen without a purulent exudate or gangrenous process irrespective of the leucocyte count. Ninety per cent. of polynuclear cells has always indicated a very severe degree of cachexia, if I may use the term, and while I had one specimen of 95.2 per cent. where recovery followed operation, all other cases in which the percentage was over 94.5 resulted fatally. It is not wise, nor will I attempt, to establish narrow arbitrary limits, but I am quoting the above figures from the 1,400 surgical cases studied in this way.

This second type, of increased polynuclear percentage, with little or no inflammatory leucocytosis, is the most interesting one, as it particularly demonstrates the value of the procedure I am advocating, and the cases are usually in urgent need of operation on account of poor body resistance. Again, I will cite but few typical ones to illustrate:

No. 1,509.—A young woman in apparently good condition. Red cells 4,208,000. Hemoglobin 72 per cent. (v. Fleischl), has severe pelvic cellulitis from streptococcus infection, and somewhat vague manifestations of an abscess with a leucocyte count of 7,200. Her serious condition could be explained clinically by the intensity of the inflammatory process, but the polynuclear percentage of 87 indicated the necessity for immediate operation, which revealed a large collection of pus, and was followed by recovery.

No. 12,331.—A rather feeble elderly lady. Red cells 4,400,000. Hemoglobin 70 per cent. (v. Fleischl), with typical clinical evidences of appendicitis, where the attending physician and consulting surgeon advocated operation, but the consulting physician advised waiting. Leucocytes 13,200. Polynuclear cells 82.4 per cent. Owing to the latter feature, the surgeon insisted on operating, and found a perforated gangrenous appendix and spreading general peritonitis.

No. 13,702.—A young man apparently in good condition. Red cells 4,820,000. Hemoglobin 80 per cent. (v. Fleischl), convalescing from purulent otitis media and mastoid involvement, which had been operated, began to have evidences of meningeal irritation, with but slight clinical manifestations of acute inflammation. Leucocyte count 11,900. Polynuclear cells 82.3 per cent. Immediate operation revealed large abscess, and patient subsequently died of meningitis.

Third.—An increased relative percentage of polynuclear cells with a decided inflammatory leucocytosis. Most of the cases of inflammatory lesions, with or without purulent exudate, meet the specifications of this class. Here, as in the last series, the percentage of polynuclear cells was found an accurate guide to the status of the inflammatory lesion, and the figures quoted above apply here as well.

I have selected a few cases, each one of which shows one of the detailed characteristic features.

No.	Leucocyte Count.	Polynucl. Percentage.	Clinical Diagnosis.	Subsequent Course.
12,450	10,200	75.5	Cholecystitis.	No abscess or gangrene.
12,542	16,900	70.3	Pelvic Cellulitis.	No suppuration.
12,581	20,200	89.8	Appendicitis.	Perforation. Death from peritonitis.
12,616	18,700	71.0	Appendicitis.	No operation. Prompt recovery from attack.
12,622	21,500	74.0	Cellulitis of toe.	No abscess.
12,964	19,300	87.1	Appendicitis.	Gangrenous. General peritonitis.
13,223	29,800	95.2	Appendicitis	Gangrenous. Operation and recovery.
13,391	20,800	70.7	Appendicitis.	No operation. Prompt recovery from attack.
13,421	15,200	84.1	Appendicitis.	Gangrenous. Operation. Recovery.
13,428	15,800	89.9	Appendicitis.	Gangrenous. Operation. Recovery.
13,702	11,900	82.3	Mastoid.	Abscess. Operation. Recovery.
13,748	15,700	81.6	Double Mastoid.	Abscess. Operation.
13,779	17,800	89.8	Appendicitis.	Gangrene. Peritonitis.
13,861	17,900	68.1	Appendicitis.	No operation. Prompt recovery from attack.
13,927	9,100	82.2	Appendicitis.	Gangrene. Operation. Recovery.

This table could be continued at length, but the above sufficiently illustrates the value of the advocated procedure.

The body resistance toward the infection is a most important point, and while the clinical manifestations are usually a good guide, this is by no means invariable. Good resistance—marked leucocytosis; poor resistance—little or no leucocytosis, is the old rule. A. M. Holmes[9] published a few days ago, a very interesting article on the nature and significance of leucocytosis. He judges body resistance by the small lymphocyte count. As stated above, the leucocytosis with a given percentage of polynuclear cells, is, I believe, the best indicator of this body resistance, when we accept the theory that the polynuclear percentage is the index of the degree of the inflammatory lesion.

For example, a patient has an inflammatory lesion without purulent exudate, and a polynuclear percentage of 75. If his leucocyte count is 25,000 the body resistance is much better than if the count is 10,000. Another case has an acute inflammation with abscess, and a polynuclear percentage of 84. If the leucocyte count is 30,000 the body resistance is much better than if the count is 15,000. The severely toxic patient with 92 per cent. polynuclear cells is combating his disease with greater energy and success if he has 40,000 leucocytes in 1 c.mm. than if they are only 20,000; and should the leucocyte count be 7,000, this is a clear indication of an absence of all systemic effort to overcome the infection. My records show many examples of the truth of the above assertion.

Iodophilia, or the iodine reaction, is noted in the blood in all inflammatory lesions, and its presence as well as intensity have been used as a guide to the character and severity of the inflammatory process.

Locke[10] is probably the most ardent advocate of this method, and his results merit close study. Other observers have not been so well satisfied with it, and find it difficult to recognize the different degrees of intensity in the reaction. I must confess that in my hands the results do not seem nearly as reliable as those obtained from the polynuclear percentage as detailed. A distinct iodophilic reaction is always obtained in a pronounced leucocytosis, and would erroneously indicate the presence of a suppurative process, while the polynuclear percentage would lead to a much more accurate conclusion. This error would be most likely in the class of cases which I have mentioned in Group I.

In carcinoma there is oftentimes a leucocytosis

and an increase in the percentage of polynuclear cells on differential count, and these features were at one time supposed to be of value in diagnosis. Since these assertions were made the literature has been flooded with communications citing cases of cancer in which the number and relative proportion of leucocytes are unchanged. The consensus of opinion at present is, that the leucocytosis and polynuclear increase observed in many cases of carcinoma are due to the secondary infection, thus being a guide to the extent of the accompanying inflammatory process, and no indicator of the nature or extent of the primary lesion.

The arbitrary rule, that no surgical procedure is to be undertaken when the percentage of hemoglobin is below 30 is also in need of amendment. Determination of the amount of hemoglobin in these specimens poor in coloring matter is a very crude matter, and opinions concerning any operation in cases of severe anemia are much better when based on the complete blood picture, than if a necessarily crude estimate of the amount of hemoglobin alone is considered. The chlorotic girl with 30 per cent. hemoglobin, 4,500,000 red cells, a normal leucocyte count, and perhaps a slight relative lymphocytosis on differential count is certainly in much better condition to withstand an imperative operation than the case of secondary anemia, with 50 per cent. hemoglobin, but only 2,000,000 red corpuscles, a marked leucopenia, and a high relative lymphocytosis.

One more item before closing. Cases of acute leukemia in which a sudden increase in lymphatic tissue, interorganic hemorrhages, or both, with temperature and other clinical evidences, often closely simulate acute inflammatory lesions, and therefore are brought to the attention of the surgeon. As every article in the literature on this subject details one or more cases of this kind, it is not necessary to quote special references. While such operation can but hasten the invariably fatal outcome of these cases, an error is disagreeable, and this one is rapidly disappearing, solely because a blood examination, in this instance at least, establishes a correct diagnosis.

PRELIMINARY REPORT ON THE TREATMENT OF CHRONIC DYSENTERY, BY IRRIGATION OF THE COLON THROUGH THE VERMIFORM APPENDIX OR AN OPENING INTO THE CECUM.

By WM. H. ARTHUR, M.D.,
SURGEON, U. S. A., SOLDIERS' HOME, WASHINGTON, D. C.

THERE are very few surgeons in the army, who have had any tropical experience during or since the Spanish war, who have not met with a large number of cases of chronic dysentery, which have resisted treatment, and persist as dysentery, or have led to a condition of chronic colitis, with more or less extensive ulcerations, confined practically to the great intestine. These cases after undergoing the various methods of treatment with ipecac, quinine irrigations, long-continued strict dieting, rest, etc., reach a stage when they are fairly comfortable in hospital, but promptly relapse when they try to do any work or live on ordinary food. As many of these cases occur in young men, more or less ambitious, and anxious to get out of hospital and enjoy life; and as the results of all the methods hitherto suggested have been very unsatisfactory, anything that promises permanent relief is worthy of a thorough trial. A number of these cases after having exhausted the skill and ingenuity of their post surgeons, are discharged on surgeon's certificate of disability and drift into the Soldiers' Home, the last resort of the broken-down enlisted man of the regular army.

The most promising and rational treatment of chronic dysentery, and the bowel lesions left by it, was formerly the high rectal irrigations, carried out systematically and in some of the less severe cases, where the lesions were not too extensive, this seemed to have some beneficial effect. No hospital in the Philippines, however remote, was, or is complete without a good supply of rectal tubes and fountain syringes. This rectal irrigation, however, is not satisfactory. It is doubtful if the fluid ever reaches beyond the splenic flexure of the colon, and it soon becomes very distressing, and in many cases sets up a painful proctitis. The patients complain bitterly of the discomfort they suffer, and the treatment must be kept up a long time to effect any result; and a great many cases fail to improve except very temporarily, after the most persistent rectal irrigations.

I think it was Weir of New York, himself an ex-army surgeon, who first suggested the irrigation of the colon from the caput coli, utilizing the appendix as a tube through which to introduce the irrigating fluid.

While in New York in 1902 I saw Dr. McCosh of the Presbyterian Hospital perform the operation, and a patient upon whom Dr. Dawbarn had done it was shown at the Academy of Medicine, and good results were claimed in both cases. It certainly seems a rational method of getting at the seat of the trouble, the principal difficulty being that, if the ulcerations and cicatrizations are very extensive, a complete cure would be almost beyond hope. Still it was certainly worth trying, and a case coming under observation here, I operated, with such a good result, that I was encouraged to do it in other cases.

The first man upon whom I tried it was a young ex-soldier who had been treated off and on for three years. He had acquired the disease in the Philippines, had been discharged and finally reached the Soldiers' Home in very poor condition. He was emaciated, weak, unable to stand any active exercise or eat any but liquid food without bringing on a bloody-mucous diarrhea, not very painful, but debilitating. When I first saw this man he was having four to six stools a day, containing still a few active amebæ, blood, and mucus. Like many others, he could be kept tolerably comfortable by rest in bed and strict dieting. Any active exertion or attempt to eat solid food caused prompt relapse.

The operation was done July 27, 1903. It was found that the appendix was tied down in a mass of adhesions, and the cecum was so friable from ulcerations that any attempt to bring the appendix out through the wound was liable to do injury to the colon, so it was abandoned. The colon, just above the ileocecal junction, was stitched into the wound and forty-eight hours later opened, a catheter introduced and irrigations commenced. To destroy any lurking amebæ, a 1-2,000 quinine solution was used, 500 c.c. being poured in twice a day for six weeks. (Ice water and hydrogen peroxide 10 per cent. were tried in two subsequent cases, but the former caused some distress and depression, and the latter intestinal

distension from formation of gas, and quinine solution is now depended on to destroy amebæ.) Examination of stools failed to show any amebæ after that period, and for six weeks more the same amount of a ¼ per cent. solution of silver nitrate was used. This patient improved rapidly and steadily, but he developed symptoms of insanity and was sent to the Government Hospital for the Insane. The fecal fistula closed spontaneously. He was discharged from St. Elizabeth's and went to his home. Within a month I have received a letter from him, stating that he is in excellent health, eighteen months after operation.

On October 4, 1904, the next patient was operated on. This patient was a large man of heavy frame, weighing 164 pounds, but he had five to eight bloody stools a day, loaded with motile amebæ containing red blood corpuscles. This case was similar to case No. 1, in one respect, *i. e.* the appendix was not freely patulous and it was necessary to do a colostomy. The results in this case have been excellent to date, three months after operation. The irrigations were discontinued January 2. The patient has gained 26 pounds, his stools are formed, his diet is unrestricted, and he is now employed as an orderly in the hospital.

Patient No. 3 was operated on December 1, 1904. At the time of operation he weighed 138 pounds. The appendix in this case was non-adherent and patulous, and the case presented no difficulty. It was brought out through the wound, stitched to the skin at three points, the sutures, of course, not being allowed to encroach on the lumen of the appendix, and forty-eight hours later the protruding part of the appendix (about two inches) was cut off, catheter introduced and irrigation begun. Five weeks after the operation this man had gained 15 pounds. He has stools only after irrigation. His general appearance is already markedly better, his complexion has changed from very sallow to a healthier color, and he has a feeling of general bienaise. His diet is not entirely unrestricted, but he can digest solid food in small amounts, and is entirely free from the distressing abdominal distension that before operation followed the ingestion of even the most easily digestible food. Altogether the case promises well, though it is too early to pronounce him cured.

Two more cases have been subsequently operated on, but as one was undertaken only a week and the other three days ago, it is impossible as yet to give a prognosis. In the first of these it can be said that the irrigations are not only painless, but that the patient says he feels better after each administration of the solution (quinine 1-1,500), and has asked for three instead of two irrigations each day.

The operation, if the appendix is not firmly bound down and is freely patulous is very simple for a surgeon, who is at all used to abdominal work. The usual incision is made as for appendectomy, the appendix is stitched to the skin. It may be a good idea to scrape the appendix slightly with a scalpel before stitching, where it comes in contact with the abdominal wall to ensure and expedite firm adhesions. The abdominal wall is securely stitched, layer by layer, down to the point where the appendix comes through, *i. e.* the lower end of the incision. Forty-eight hours later the protruding appendix is cut off, catheter introduced and irrigations begun at once. In a week all stitches are removed, the irrigating tube is left in, secured with a pinch cock, and changed from time to time as it becomes worn out.

It is not claimed that a cure has been found for all these distressing cases. The number treated here, five in all, with two just started, is, of course, too small to derive any safe conclusions from, but the treatment seems reasonable, and so many of these cases come under observation nowadays, that it is suggested that the operation be performed in a sufficient number of cases to test thoroughly its value. It can do no harm and offers a good chance of relieving a very distressing condition.

The advantages of this method of irrigation over the deep rectal injections are:

1. The irrigating fluid is delivered first at the point shown by experience at the post-mortem table to be the location of the most extensive lesions, and is carried from there by the natural peristaltic movement of the colon to the outlet. Rectal irrigations, to reach even the transverse colon, must overcome this natural tendency of the bowel to drive out any foreign substance.

2. It is entirely painless, and very much easier for the nurse to administer. Indeed, the patient can soon be taught to do the irrigating himself.

3. It is possible to keep it up much longer, for it is my experience that rectal irrigations soon become so distressing that they must be discontinued for long periods.

Very little, so far as I know, has been written on the subject. I would earnestly recommend that it be given a trial, as it certainly is rational in theory, easily done, and so far as a few cases can prove anything, has had good results.

When the tube is finally withdrawn, if the opening does not close spontaneously, it is a simple matter to loosen the adhesions around the appendix, draw it out, ligate, cut off, and sterilize the stump with the thermocautery point, and drop it back, closing the small opening in the abdominal wall with a single suture carried rather deeply.

The diet of these patients after operation is very gradually increased, a careful watch being kept to see if diarrhea returns. The irrigations are not discontinued until the patient can eat solid food without discomfort or any tendency to relapse, and is passing formed stools. He should be allowed to eat several meals of solid food as a test, before irrigations are finally discontinued and the fistula closed.

It is, I think, a good plan to allow the tube to remain in place without irrigations for a week before finally removing it. If the symptoms recur, irrigations can then be resumed. It seems to be safe, after a week without irrigation has gone by, the patient being on unrestricted diet and passing formed stools, to remove the tube and close the fistula.

Since writing this paper a sixth case has been operated on, January 20, 1905, and the patient is already improving and anxiously looking forward to the time when he may re-enlist.

I would add that the very careful, thorough, and intelligent after-treatment of these cases by the house surgeon, Dr. J. E. Meisenhelder, has been of great assistance in securing favorable results. Indeed, the operation itself is only the first step in the treatment. which, after all is said, is still in the experimental stage.

A WARNING AND A PROTECTOR FOR X-RAY WORKERS.

By ARTHUR HOLDING, M.D.,

NEW YORK.

RADIOGRAPHER, CORNELL UNIVERSITY MEDICAL COLLEGE DISPENSARY.

RECENTLY the medical profession and the public were startled by the announcement of the death of two *x*-ray workers, due to carcinoma developing on their hands and forming metastases. Although repeated amputations were performed, yet the morbid process was not controlled. Since that time similar

malignant neoplasms have developed on the hands of four well-known experts, and they have submitted to one or more amputations. On the hands of seven other *x*-ray workers, intractable, deep-seated, and suspicious ulcers, some of them causing pain in the underlying bone on pressure, have been present for months. The lesions show little tendency to heal under careful and faithful treatment. These cases are simply instances which have come under the writer's personal observation; doubtless there are

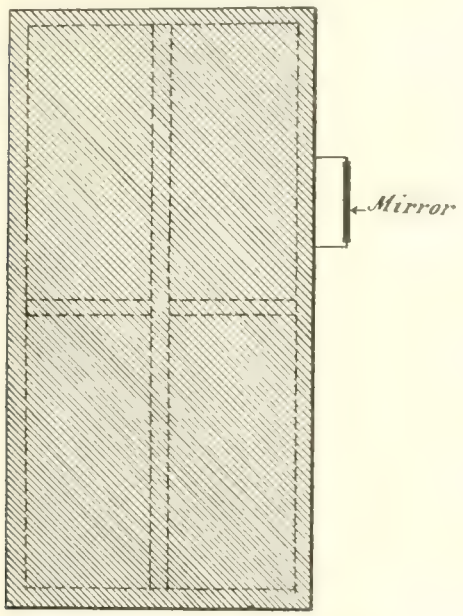

Fig. 1.—Lead Protecting Screen for X-ray Work.

many more. Through a feeling of delicacy, attention is not usually called to such cases, except in obituary notices. In one case, an epithelioma, which was verified microscopically, healed after complete withdrawal from the rays and under careful local treatment.

On the very heels of this announcement of martyrs to science, the pathetic domestic details of which are here omitted, another surprise comes. Examination shows an azoospermatic condition among *x*-ray operators, even in some instances in which the radiologist has taken precautions to avoid needless exposure to an active tube by (a) directing the rays away from himself, (b) refraining from all fluoroscopic examinations, and (c) not remaining in the same room during radiotherapeutic treatments.

While the prospect of sterility is a shock to the individuals affected, particularly as they are usually unaware of any such change having occurred, the question of perhaps graver moment is, "What will develop next?" Röntgen's discovery was made a decade ago.

Those *x*-ray workers who have died from carcinoma were men who were among the earliest observers in this field, and the carcinomas developed in parts long exposed to the action of the rays. More recent workers, profiting by having seen these ulcerated hands, denied themselves the mysterious observations of their own bones seen by looking at their hands with the fluoroscope, and instead, looked through the patients' chests, or used various skiameters. Later, when a roughened condition of the skin about their eyes and over the bridges of their noses developed, even fluoroscopic examinations were abandoned. And yet the attacks of the insidious rays are not parried. Experiments on animals have shown that the earliest effects of exposures to the *x*-rays are shown in the lymphatic system, resulting in a degeneration and absorption of the lymphatic glands, also a degeneration of the Graffian follicles of the ovary, and epithelium lining the seminiferous tubercles of the testicle. It would behoove those who are subjected to the rays to note whether they can palpate their superficial glands; for instance, those in the inguinal region, which are normally palpable. What will the second decade of Röntgen's discovery reveal to us?

In the *x*-ray we have an agent which also causes dermatitis, the so-called "burns" of first, second, and third degrees, expoliation of the hair, nails, and other skin appendages, capillary endarteritis, telangiectasis, shows selective destructive action on the higher specialized cells (such as those in the sweat and sebaceous glands and hair follicles), and stimulates the lower organized connective tissue cells. This is well shown in the dry, parchment-like condition of skin long exposed to *x*-rays. Is it not possible that the cumulative effect of the prolonged exposure that the *x*-ray worker must submit himself to during years of work in the rays will result in a degeneration of the glands of the skin all over the body, and that, deprived of these important eliminative exits, the kidneys will become overworked, and subsequently become diseased? I will not pursue the field of supposition further, but these deleterious actions, and these possible dangers, should be carefully considered by all engaging in this work. The carelessness of the past may change to useless precaution in future, but certainly the *x*-ray worker should protect himself. That we have been dealing with a deeply penetrating agent has long been known; that it is also dangerous must cause apprehension.

Various protectors have been suggested, some to be worn by the operators, some to be placed on the tubes, and others to be interposed between the tubes and the operators. A metal of high specific gravity must be employed, and lead is the favorite. A lead

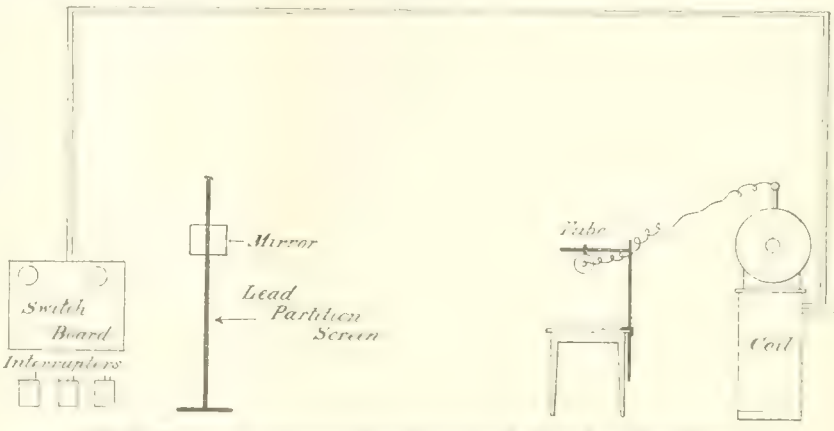

Fig. 2.—Scheme for Arranging a Lead Protecting Partition in an X-ray Room

suit of armor would be too cumbersome and heavy, while the practice of simply wearing a lead apron is insufficient protection. It will cover the abdomen and pelvis, but with an agent as powerful and dangerous as the *x*-ray has proved to be, one should not needlessly expose the liver, heart, kidneys, spleen, intestines, brain, blood, and lymphatic systems. Because of its weight, lead is also objectionable to place about a delicate glass tube, especially as most operators must judge the character of the *x*-rays by the appearance of the fluorescence of the tube, while

safety prohibits the use of the fluoroscope, and even the skiameter.*

The most feasible protector, in the writer's opinion, is a lead partition between the operator and the *x*-ray tube. Such a protector can be arranged by having the switchboard mounted on the side of the *x*-ray room farthest removed from the *x*-ray apparatus, and placing a strong oak framed screen, covered with two layers of sheet lead, each 1-16 of an inch thick, between the operator and the *x*-ray tube. This screen should be about six feet high and three feet wide. A mirror can be arranged on pivot supports at one end of the screen, so that the operator can see the reflection of the fluorescing tube, and need not look directly at it.

Such a device gives more protection than most *x*-ray workers have been using in the past. It is too early to say whether it will secure absolute safety for the radiographer.

* Millamperemeters introduced in circuit with the tube may relieve the operator from even seeing the tube.

125 West Fifty-eighth Street.

Notes on "Climatic" Bubo.—F. H. A. Clayton calls attention to the fact that the etiology of this affection is still largely a matter of speculation. He cites several cases of indolent chronic buboes. The first patient looked anemic, though the hemoglobin was not measured. In the differential blood count the eosinophilia were estimated at 22 per cent. The motions were examined for parasites, but none were found. The bubo was in the right groin, with no apparent cause. Later, a patch of dhobie itch in the perineum was discovered, and the patient admitted having had it at intervals for some time. Thus a quiescent focus of irritation was present. Two other cases of indolent chronic buboes were cited without obvious cause, although neither patient was especially anemic, nor had any febrile symptoms. Another case had the horizontal glands in both groins enlarged. The only possible source of irritation was some indurated papules on the thighs, the remains of a severe attack of furunculosis of the previous year. None of them, however, showed any signs of activity. The temperature was elevated, but the patient was perfectly comfortable. He was not markedly anemic. Search was made for malarial organisms, with negative results. The glands were incised, and a tube inoculated with the pus, again with negative results. Eosinophilia was marked. The patient became very haggard and anemic looking, but the buboes finally healed and the patient recovered. Two of these patients were at Wei-hai-Wei, and two at Hong Kong. The writer, in seeking for the cause of these buboes, states that venereal disease can be definitely excluded in all of these cases. So can any active source of irritation, in the area drained. In three of the cases, however, there were the remains of what had been foci of irritation, quiescent at the time, nevertheless. The writer believes this to have had some part in determining the localization of the adenitis. By itself, however, it was not capable of causing the condition. These glands do not of necessity suppurate. When this does occur, it is indolent. Cantlie believes that these are really cases of pestis minor and allied to true plague. In the fourth case, repeated examination showed no organism resembling that of plague. The possibility is suggested that the phenomena here discussed are produced by some circulating toxin, whether or not originally manufactured by bacteria. The localization of the enlarged glands might then be readily determined by some previous irritation or trauma. This would explain the common involvement of the inguinal glands. Although bacteriological evidence is valuable, isolation of even a definite organism does not prove that it is the cause of the condition.—*The Journal of Tropical Medicine.*

The Management of Acute Peritonitis.—J. Garland Sherrill speaks of the two forms of infection—acute septic peritonitis and general suppurative peritonitis. In the first form, the patient dies from a profound toxemia before the local changes have progressed to the point of pus formation. In the second form, pus is found free in the peritoneal cavity without any localization of the process. Many cases result fatally, especially those of the septic type, regardless of the time when they are seen or the treatment employed. Various lines of treatment have been advocated. This is generally considered a bacterial disease, and various forms of organisms have been found in different cases. At the beginning it is always a local infection, and in the large majority of cases the treatment is surgical. In cases due to perforating ulcer of the stomach, absolute rest of the stomach is indicated. Enemata should be used to unload the lower bowel and relieve meteorism. Colon lavage is safe, followed by nutrient enemata as indicated. The use of heat or cold locally can be tried. When the perforation is lower down, and in cases of obstruction with danger or possibility of a rupture, gastric lavage can be safely employed, but purgation and enemata are very dangerous. Nothing should enter the stomach after it has been cleansed. Small enemata can be used to empty the rectum, and small nutrient enemata may be given at proper intervals. In cases which follow puerperal infection, surgical operation, the rupture of an abscess, and rupture of the appendix, a different plan of treatment should be employed. In the latter condition, in ruptured abscess, and in post-operative cases, purgatives are indicated. A large source of infection can be removed by elimination of the feces. Leeching is perhaps worthy of trial in cases of peritonitis. Careful stimulation should be given in all forms. As to surgical treatment, great stress should be laid on operation as a measure for the prevention of general peritonitis. The writer declares that the outcome of a case will depend upon the following factors without reference to the special steps in the operation or the subsequent care: The virulence of the infection, the quantity of the infecting medium, the resistance of the patient, the activity of the eliminating organs, the time at which the patient comes to operation after the poison enters the cavity, the dexterity and thoroughness of the surgical procedure, no matter what the method. In cleansing the abdomen, the writer prefers the method of flushing. The septic form of this disease demands very early operation. Otherwise it should be treated like the suppurative type. After operation these cases should be managed like any other abdominal section.—*Annals of Gynecology and Pediatry.*

The Absorption of Carbon Dioxide from the Stomach.—Loening says that although a great deal of work has been done on the therapeutic effect of beverages containing carbon dioxide, but little is known as to the actual behavior of the gas when introduced into the stomach. Several authors have published observations on the question, but their results are conflicting and incomplete. He introduced varying quantities of distilled water charged with the gas into the stomachs of dogs and of patients, and after longer or shorter intervals determined the amount of gas that had been absorbed. The experiments showed that the stomach possesses to a marked degree the property of absorbing carbon dioxide in the presence of water. Absorption is very prompt, so that over half the gas is taken up during the first five minutes and three quarters at the end of from ten to fifteen minutes. After this, absorption becomes very slow, and after an hour only a very small residuum of the gas remains, which is taken up very slowly or not at all. This is in accord with the observations of Schierbeck, who found that the stomach gives off carbon dioxide if filled with water entirely free from the gas. Experiments conducted with carbonated alcoholic beverages gave similar results. The observations also demonstrated the fact that the stomach appears to be wholly incapable of absorbing water.—*Zeitschrift für klinische Medizin.*

COPPER SALTS IN THE PURIFICATION OF WATER SUPPLIES.

THE use of copper salts to purify water has not as yet been tested on a sufficiently wide scale to admit of a definite opinion being formed as to its value. To condemn utterly the method would be as unwise as to offer indiscriminating praise. That these salts have their place in the list of water purifiers would seem to have been more or less proved, but at the same time that their use is limited would appear to be just as obvious, and that their extensive employment may be dangerous to the health of the community has not yet been satisfactorily disproved.

The *Yale Medical Journal* for February, 1905, contains an article by Professor H. E. Smith, in which the matter is discussed at some length. The writer draws attention to the fact that the practical value of copper salts has been demonstrated as regards the destruction of certain organisms which pollute public water supplies, and especially of the most troublesome and common of these such as the various confervæ. These appear to be readily destroyed by copper sulphate in dilutions of one part in from one to ten million parts of water. It is stated that during the past year fully fifty reservoirs have been thus treated, the method having been successful in controlling the objectionable growths.

As Professor Smith points out, however, there are two questions which naturally suggest themselves, viz., what becomes of the copper? and what danger is there of copper poisoning to the people using a copper-treated water? As to the fate of the copper little definite information can be obtained, but from evidence gathered Professor Smith thinks we may conclude that there is a tendency for the copper to disappear rapidly from solution, and that this is probably accomplished through the agency of the organisms themselves. With regard to the presence of copper salts in water as a menace to health, the writer states that "from considerations on the toxicology of copper one must conclude that there is no apparent danger from poisoning in the use of water treated with such amounts of copper sulphate as are used in the Moore method for the destruction of the most objectionable organisms, and that this would be so even if the copper remained in solution. The present limited experience confirms this conclusion as to the safety of the method, for in several cases the water has remained in use during the treatment and no bad effects have been noted."

The employment of copper salts in the purification of water supplies must be regarded rather as an adjunct to treatment, than as a practical remedy in itself. As to whether the method might be of value for the destruction of pathogenic organisms can only be a matter for surmise. True it is known that copper sulphate has a destructive action upon typhoid bacilli and cholera germs in water, but these facts have been gathered chiefly from laboratory experiments, and under conditions which do not ordinarily prevail in water reservoirs, and it would be distinctly unwise at present to trust solely to such means for purifying public water supplies, in spite of reports made from time to time, of the apparent success of the method in various places. Other well tested methods must still be relied on, while copper salts might possibly be used under certain precautions in the emergency treatment of a polluted water supply.

MILITARY HYGIENE.

PREVENTION of disease is the watchword of medical practice in these days. General hygiene has made great strides within the past few years, so much so, indeed, that in certain communities in which its principles have been carried out carefully and thoroughly, typhoid fever has practically ceased to exist. But although satisfactory progress is being made in the hygiene of civil life, it can scarcely be stated with truth that a corresponding advance is going on in military hygiene. Modern armies in times of war are still decimated by typhoid fever and other preventible diseases, albeit in the present struggle, the Japanese Army Medical Department would seem to have come nearer to a successful solution of the problem than has been reached by the Army Medical Service of any other army. Nevertheless, so far as military hygiene, generally speaking, is concerned, the science is yet in its elementary stage.

The *Journal of the Military Service Institution* for January and February, 1905, contains a paper on military hygiene by Captain Peter E. Traub, being the Seaman prize essay. In this paper it is clearly shown that little or no attention is paid to the subject either at West Point or at Annapolis, and that of the Postgraduate schools, only the Infantry and Cavalry School at Fort Leavenworth, Kansas, makes any effort to give adequate instructions in military hygiene. Captain Traub advances the following conditions, the carrying out of which would tend to promote the intelligent practice of military hygiene in our army. (1) If the Medical Corps of the army succeeded in securing and retaining the best young doctors obtainable from civil life, and if, after entry into the corps, these doctors were made so to devote themselves to study and practice as to become and to show that they were experts in military, sanitary, and hygiene matters. (2) If the line officers from the second lieutenant to the general were properly and systematically educated, instructed, and trained to meet their responsibilities in preserving the health of the men and were made to show, in their examinations for promotion, that in both theory and practice they understood and could apply this most important part of their duty. (3) If the enlisted men were, by instruction and training and discipline, imbued with a due sense of responsibility in the part they must play to preserve their own health and the health of their comrades. (4) If, in the purchase, expenditure and accounting of material and

supplies to be used in experimental, instructive, and practical purposes of demonstration of military discipline and military hygiene in post, camp, and on the maneuver field, the War Department were liberal and generous and insisted upon all subordinates taking into consideration only the welfare of the command and the preservation of health. (5) If, finally, in our field maneuvers, the War Department, the Army War College, and the commanding generals were to devote proper attention to a full development of the opportunities presented of putting into use, under conditions approximating those of actual war, all that has been learned and practised in school and post, by enlisted man, line officer, and medical officer.

Referring to the Medical Corps, Captain Traub makes the self-evident remark that it should be composed of the very best material only, and then proceeds to show that under existing conditions it is exceedingly difficult, nay, almost impossible, to obtain such material. The meager pay and slow advancement do not render the young, clever, and ambitious medical graduate eager to embrace the profession of arms. Hence, as Captain Traub points out, Congress must come to the help of the Medical Corps and remove the demoralizing effects of the Act of February 2, 1901. Having secured a sufficient regular supply of the best young physicians from civilian life, the obvious course to pursue is to train them thoroughly for their duties, and especially to instruct them most carefully in all that pertains to military hygiene.

Finally, the writer advises that line officers of whatever grade, not only in undergraduate schools, but in garrison and special service schools, the staff office, and the War College itself, should possess an adequate knowledge of military hygiene. They should know how preventable diseases are propagated, and should be well trained in the best methods of checking and obliterating the same.

But however good may be the mental equipment of the officer with regard to hygiene, unless he is to some extent assisted by a corresponding knowledge and by a sense of responsibility on the part of the enlisted man, his efforts will either come to naught or at any rate be greatly hampered. This is in fact the crucial point. If the rank and file can be induced to take an intelligent interest in the preservation of their own health and that of their fellows, the victory is practically won. Unfortunately, but a small percentage of the privates do take any such interest, the large majority exhibiting a careless disregard of matters sanitary. In the German army the irresponsibility of the ordinary soldier is offset by the rigid discipline that therein prevails. He obeys his officers implicitly, and for this reason there are less ill-health and fewer epidemics in the German army than in any other except the Japanese army. With the American enlisted man things are on an entirely different footing. He is, perhaps, on the whole more intelligent and better educated than the soldier of any other nation, but he is notoriously impatient of control. Thus the only mode of reaching him is by developing his moral responsibility and appealing to his better feelings. When a man knows that by carelessness he will not only imperil his own life, but possibly the lives of hundreds and thousands of others, then he will pause ere committing such an action.

Captain Traub suggests that officers, and the rank and file to a certain extent, be instructed in hygiene, the former at the military schools and the latter by a process of practical education which will teach them how to fight preventable disease, and will at the same time tend to develop moral responsibility.

The efficiency of an army is largely dependent upon hygiene and preventive medicine. As a celebrated military leader once said, "To keep the troops in good health is more important than to patch them up." There is a real need in the United States army as in other armies, of paying particular attention to hygiene. The question of preventing disease should be studied during the time of peace, so that if war comes, an army may be prepared to meet any conditions

---

The California Vaccination Law Upheld, Several weeks ago, both branches of the legislature of California by a small majority passed a bill nullifying the law which for several years has required the vaccination of all children as a condition to their attending the public schools of the State. Since that time, the bill has awaited the signature of Governor Pardee. But the Governor has refused to sign it, and the senate, by a vote of 22 to 3 has refused to pass it over his veto. The antivaccinationists are astonished, for they could see no question of principle or duty in the action of the Governor, and looked for him to show what is called the courtesy of a politician toward the influence which had enabled them to carry their measure through the legislature. The medical profession is justly proud, not that the law requiring compulsory vaccination has been permitted to remain operative, but that Governor Pardee is still Dr. Pardee, a physician of integrity. The following paragraphs from the Governor's message of veto are noteworthy for the clear expression of the principle involved in the vaccination question: "Before the discovery and application of vaccination by the immortal Jenner smallpox was nearly universal, and it was considered to be a grave disadvantage not to have had the disease in childhood. Severe and terrible epidemics have gradually but surely become things of the past, except when from any cause vaccination has been neglected. That accidents of many kinds, even death, may follow vaccination is not and cannot be denied. But that the number of these accidents, compared to the many, many thousands—even millions—of times which this beneficent procedure is practised, is anything but infinitesimal is not borne out by the facts. When vaccination is compulsory, and the law is well administered, there is but little smallpox; so little that those protected by vaccination soon lose their fear of the dread disease; and turning out attention to the lesser evils of the vaccine virus, many of us conjure a fear, not warranted by facts, against the very thing that saves us from a much worse fate. This, I think, is what has called into being the bill which I now return to you unsigned. Were it to become a law, there can be no doubt that vaccination would soon fall into practical disuse. And thus would be prepared among our children (not mine, for they shall always be protected) a field for smallpox to fairly revel in."

Dr. F. W. Draper, for twenty-eight years medical examiner for Suffolk County, Mass., has given notice of his intention to resign on June 30.

Epidemic Infantile Paralysis.

Dr. George F. Still writes in *The Practitioner* for February, 1905, reviewing some recent work in diseases of children. Referring to epidemic infantile paralysis he points out that several epidemics of this disease have been recorded within the past ten years, and that their occurrence is generally considered to support the view that the condition is an infective disease due to some specific materies morbi. The writer draws attention to the opinions of various observers in this and other countries with regard to the malady, and states that there would seem to be a possibility worthy of consideration in such an epidemic as that in Vermont, described by Calverly, in the Medical Record, Vol. 46, page 671, in which the mortality was over 10 per cent., namely, that the disease was cerebrospinal meningitis. Dr. Still thinks that so far as any bacteriological evidence has been obtained, it would seem to make the distinction between infantile paralysis and cerebrospinal meningitis less clear. In one case of supposed infantile paralysis in which lumbar puncture was done by Schultze (Münchener medizinische Wochenschrift, Vol. 28, p. 1197) diplococci were found in the cerebrospinal fluid resembling the diplococci of cerebrospinal meningitis. No growth, however, was obtained in the culture. Views on this point are divergent and Dr. Still is of the opinion that, however, strongly the clinical evidence may point to a specific infection as the cause of infantile paralysis, it is certainly not conclusive, and that the epidemic occurrence, from which most clinching evidence might be expected, has by no means settled the question, which therefore still remains *sub judice*.

Tent Treatment for the Tuberculous Insane.

The plan of treating the consumptive insane in tents has now been practised by Dr. A. E. Macdonald, Medical Superintendent of the Manhattan State Hospital, East, for several reasons, and is fully described by him in a pamphlet reprinted from a Directory of Institutions and Societies dealing with tuberculosis in the United States and Canada. The results obtained from the tent system of treating consumptives have been conspicuously successful, and the author summarizes as follows: "The isolation of the tuberculosis patients has reduced to a minimum the danger of infection of other patients and of employees. The patients themselves have suffered no injury nor hardship, but have, on the contrary, been unmistakably benefited. This is shown among other ways by a decrease in the death rate from pulmonary tuberculosis, both absolute and relative, and by a marked general increase in bodily weight, amounting in the case of one patient to an actual doubling of weight—from eighty-three to one hundred and sixty-six pounds—in fourteen months of camp residence." Dr. Macdonald considers the success attending the tent treatment of consumptive insane at Ward's Island a refutation to a great measure of the theory that the consumptive man is doomed unless he can at once abandon home and family and business and betake himself to some remote region.

The Perennial Violet.

Violet leaves form a favorite lay cancer remedy, and reputed cures are reported at more or less regular intervals. The latest case is one described in *The Lancet* by Dr. William Gordon, a physician in a Devon-Exeter Hospital, and it is said to have aroused considerable public interest. Violet leaves used as a poultice or fomentation externally and taken in the form of decoction internally, are said to have effected, in about four months, a cure of what five physicians called cancer of the tongue, but, as usual in such cases, no microscopical examination of the growth was made.

News of the Week.

The Garcia Celebration.—In order to make the date of the local Garcia celebration coincide with that held in London, the March meeting of the Section on Laryngology of the New York Academy of Medicine was held on the evening of the 17th inst. Dr. James E. Newcomb presented a biographical sketch (see page 441), dwelling on the early training of Señor Garcia and his experience as a teacher. Allusion was made to certain incidents connected with his visit to this country in 1825 and attention was also called to the remarkable preservation of his mental and physical powers at his advanced age. The second speaker was Mr. Hermann Klein, music teacher and critic, who had been for thirty years a friend of the great teacher and was formerly his pupil. Mr. Klein lived for some years in the same house with Garcia, and he gave many interesting reminiscences of this intimate association. Garcia's peculiarities at a teacher were dwelt on and reference made to his own estimate of his great invention. The last speaker was Dr. John N. Mackenzie of Baltimore, who took as the subject of his address the Future of the Laryngoscope and the Study of Laryngology. Dr. Mackenzie spoke of the difficulties which had beset the early teaching of the specialty in this and other countries and gave an account of the system of instruction which had been elaborated in the Johns Hopkins University, in which institution he holds this special chair. He believed that the time to begin this work was during the undergraduate period when the student was pursuing other special studies and was more likely to appreciate the relation of a part to the whole. On this foundation more detailed special work could be built up at a later period. He believed that laryngology should be everywhere made a required study and counted as a requisite for a medical degree. The time was coming, in his judgment, when every practitioner should have a familiarity with the laryngoscope comparable to that which he now has with the stethoscope and other familiar instruments of precision in diagnosis.

In London on this day Garcia celebrated his hundredth birthday in remarkably good health. King Edward, Emperor William, and the King of Spain all decorated him. King Edward received the Professor at Buckingham Palace and bestowed on him the Commandership of the Victorian Order. Later Professor Garcia attended a reception held under the auspices of the Laryngological Society, where he received an enthusiastic welcome, and the Marquis Villalobor, the Spanish Chargé d'Affaires invested him in behalf of King Alfonso with the Royal Order of Alfonso XII., while Professor Fraenkel of Berlin, representing Emperor William, presented to him the Gold Medal for Science. The Professor was also the recipient of a portrait of himself by John Sargent, and a number of congratulatory addresses. Dr. Harmon Smith offered the congratulations of the New York Academy of Medicine, and a similar communication was read from McGill University of Montreal.

The American contributions to the Garcia Fund amount to between $450 and $500. Advices from London are to the effect that the total amount raised has sufficed not only to defray the expense of the

Sargent portrait, but will enable the London Committee to present a substantial honorarium to Señor Garcia.

The Epidemic of Cerebrospinal Meningitis is gradually extending to cities east and west of New York, while in this city it shows no signs of abating. New Haven, Yonkers, Philadelphia, and Scranton, Pa., are all suffering from the ravages of the disease. Children are not the only ones attacked, and the deaths of adults are becoming more and more numerous. In New Haven Dr. James A. Moore, and in Philadelphia Dr. Albert B. Craig, have fallen victims, having contracted the disease during attendance upon malignant cases. Professor Addison E. Verrill, curator of the Yale Zoological Collection, has ventured the suggestion that the pathogenic microorganism may be conveyed to healthy persons by the bites of infected fleas. This method of infection, he thinks, would best explain the scattered and irregular distribution of the cases and the greater frequency of the disease in unsanitary localities. Dr. Darlington, Health Commissioner of New York, has appointed a commission of seven medical men to investigate the present epidemic, with a view to drawing up special prophylactic regulations. The Board of Estimate has appropriated $5,000 to defray the expenses of the investigation. The commission is composed of the following: Dr. William M. Polk, Chairman, Dean of Cornell Medical College; Dr. Walter B. James, Professor of Medicine in the College of Physicians and Surgeons; Dr. William P. Northrup, Professor of Children's Diseases in the University and Bellevue Hospital Medical College; Dr. Simon Flexner, of the Rockefeller Institute; Dr. Joshua M. Van Cott, Pathologist at the Long Island College; Dr. E. K. Dunham, Pathologist of the Carnegie Laboratory, and Dr. William K. Draper, visiting physician at Bellevue and Minturn Hospitals.

Increased Prevalence of Typhoid Fever in Philadelphia.—A steady increase in the number of cases of typhoid fever reported to the Philadelphia Bureau of Health has been noted during the three weeks of the month of March. Thus, for the week ended March 4 there were reported ninety-two cases with eleven deaths; for the week ended March 11, 178 cases with twelve deaths, and for the week ended March 18, 247 cases with nineteen deaths. The increased number of cases is especially noteworthy in wards provided with unfiltered water.

Missouri State Sanatorium for Tuberculosis Patients.—The Legislature of Missouri has passed a bill providing for the establishment of a sanatorium for the treatment of tuberculosis in its early stages. The institution will be located in the Ozark Mountains on a plot of land containing not less than 160 acres, and at an elevation of at least 1,000 feet above the sea level. The site will be selected by a commission to be appointed by the Governor, two members of which will be practising physicians. The bill carries an appropriation of $50,000, to be dispersed under the direction of the commission.

Breakdown of the Russian Medical Service in Manchuria.—A despatch from St. Petersburg to the *Petit Parisien*, dated March 14, says that some of the Russian surgeons remained at Mukden to care for the wounded who had to be left behind. The sanitary service there was completely disorganized. Chloroform and antiseptics were lacking, and the sick were piled up on uncovered railway trucks. The mortality among them was frightful. Civil doctors had been requisitioned, and were operating without cessation. The railway station at Harbin had been transformed into a vast amphitheater, where the dead, the dying, and the wounded were, so to speak, abandoned. The confusion was indescribable. The same condition of things prevailed at Tieling. Another despatch to the same journal, dated March 20, says that the mortality in the Russian army at the front is frightful. Five thousand men succumbed to wounds or disease last week at Harbin. The greater number of the railroad cars and trucks upon which the wounded are piled are brought into the station and left upon the sidings without having their human freight removed. The station exhales a terrible stench, having become a combined hospital, refuse heap, and charnel house.

Bill to Prohibit the Sale of Morphine and Opium.—A very sensible bill has been introduced into the Illinois Legislature for the purpose of regulating the sale of morphine and opium, providing that these drugs may be sold only on prescription of a duly licensed physician. One clause in the bill is that a druggist shall not refill a prescription unless so directed by the physician who wrote the original prescription. The author of the bill makes the statement that close to 50 per cent. of the inmates in State insane asylums are suffering from the effects of these drugs.

Resignation of the Lying-in Hospital Staff.—Eleven members of the medical staff and one of the governors of the Lying-in-Hospital recently sent in their resignations because of dissatisfaction with the medical director of the institution. The board of governors, with the exception of the one who subsequently resigned, sustained the medical director, and resolved to fill the places of those who had resigned with new appointees.

Appropriation Authorized to Build New Bellevue Hospital.—The Board of Estimate and Apportionment has authorized an issue of $850,000 of corporate stock, and as soon as the Board of Aldermen approves the measure, work will be begun on the new Bellevue Hospital building. The money to be appropriated is to be used by the trustees of Bellevue and allied hospitals in building the southeast wing of the proposed new building, which will provide space for 365 new beds. The entire building will cost between $9,000,000 and $10,000,000, and it is estimated that it will be completed within five years if the appropriations for the various sections of the new building are forthcoming from time to time, as required, without delay.

Civil Service Examinations for the State and County Service.—The State Civil Service Commission announces general examinations to be held April 8, 1905, including the following medical positions, for which application must be made on or before April 3. Assistant in Clinical Laboratory, Pathological Institute; Pupil Nurse, Erie County Hospital; Male Officer, State Charitable Institutions; Physician, Fourth and Sixth Grades, State Hospitals and Institutions, Regular and Homeopathic Schools; Women Physician, Homeopathic School.

Fire in the Presbyterian Hospital.—A small fire occurred early in the morning of one day last week in the administration building of the Presbyterian Hospital. The hospital employees extinguished the blaze, using the hose from a standpipe, before the firemen arrived and without waking any of the sleeping patients or officials.

Christian Scientists Not Seeking to Come Within the Law.—Referring to the attempts of mental healers of various shades of mentality and of healing

virtue to obtain a license from the State granting them permission to think therapeutically, the Christian Science Publication Committee writes us that the Christian Scientists in this State have never sought and do not now seek to gain recognition under the medical or other laws of the State.

Dr. Frank Parsons Norbury, editor of the *Medical Fortnightly*, was operated upon for appendicitis on February 23. We are glad to learn that his recovery from the disease and from the operation is now complete.

A New Training School for Nurses has been started at the French Hospital, 450 West 34th street, New York. The course is to be of two years' duration, including a two months' probationary term, and will include experience in obstetrics and diseases of children, as well as all branches of general medicine, surgery, and gynecology. Applicants are not required to speak French, but will receive instruction in the language as a part of their course.

Cincinnati Academy of Medicine.—On March 13 the installation of the newly-elected officers took place. Dr. Magnus A. Tate, the new president, in his inaugural address, urged that the older members who were secure in their hospital and college positions, should not sit content with their titles, but should write the papers which their positions and clinical opportunities enabled them to do. He outlined the work of the Academy for the coming year. The vote of the Academy was taken as to whether in the future the Ohio State Society, of which the Academy is a part, should publish its transactions in book form, as heretofore, or start an official journal. An overwhelming majority was given to the present method.

Against Cigarettes in Wisconsin.—A drastic anti-cigarette bill passed the Wisconsin Senate on St. Patrick's Day. It had previously been passed by the Assembly. It makes unlawful the sale, gift, or importation into the State of cigarettes or cigarette materials.

The New Mount Sinai Hospital of Philadelphia was formally dedicated on March 12 with appropriate ceremonies. The new building is a four-story and basement brick structure, situated in a populous district, and well equipped for dispensary work and the indoor care of patients.

Dr. Antonio Fanoni of this city has been made a Knight (Chevalier) of the Order of the Crown by the King of Italy.

"The Journal of Experimental Medicine," formerly edited by Dr. Welch of Baltimore, will hereafter be published under the auspices of the Rockefeller Institute for Medical Research, New York, and will be edited by Drs. Simon Flexner and Eugene L. Opie. The scope of the *Journal* will suffer no alteration by reason of the change of management, and it will continue to cover the field of experimental medicine. It is proposed to issue numbers of the *Journal* at bimonthly intervals, six numbers to constitute a volume.

Bequests to Hospital.—By the will of the late Miss Helena Hubbell of Philadelphia, the sum of $5,000 is bequeathed to the Trustees of the University of Pennsylvania for the endowment of a free bed in the D. Hayes Agnew Memorial Orthopedic Ward in the University Hospital. By the will of the late James Dundas Lippincott of Philadelphia the sum of $5,000 is bequeathed to the Children's Hospital as a memorial to his mother, Agnes Dundas Lippincott. The bulk of the estate is devised to the widow and a nephew, on the death of whom without issue it is to be divided equally between the Pennsylvania, University, Jefferson, and Episcopal Hospitals.

The Eastern Illinois Ophthalmological and Otological Society was organized in Danville, Ill., at a meeting held March 7. The following officers were elected: *President,* Dr. Cassius M. Craig of Champaign; *Secretary,* Dr. Chas. P. Hoffman of Danville; *Committee on Fee Bill,* Drs. I. E. Huston and Elbert E. Clark of Danville.

Bill to Prevent the Solicitation of Damage Suits.—A bill has passed the Legislature of Illinois which prohibits attorneys from soliciting personal or other damage cases. It was introduced by a Mr. Burnett, after having been endorsed by the State Bar Association. It is directed largely against shyster lawyers who are constantly on the search for cases of this character against members of the medical profession.

Spitting in Street Cars.—At a recent meeting of the Maryland Society for the prevention of tuberculosis held in Baltimore, Dr. John S. Fulton presented cards which he had prepared for distribution among the public. The object is to collect "sputistics" regarding expectoration in public places, and those interested are requested to fill out the cards as a record of their observations and mail them to the secretary of the society.

An Academy of Medicine in London.—The project of uniting all the medical societies of London into a Royal Academy of Medicine, of which each society will form a section, has been revived, with good prospect of being carried into effect.

Dr. Osler's Successor.—It is reported that Dr. William T. Councilman will be recalled to the Johns Hopkins from Harvard, where he is now professor of pathology, to fill a vacancy created by the removal of Dr. Osler to Oxford. Whether Dr. Welch will take Osler's chair, Councilman taking Welch's, or whether Councilman himself will take the chair of practice vacated by Osler, is not stated. Dr. Councilman was formerly at the Johns Hopkins, and went from there to Harvard a few years ago.

Obituary Notes.—Dr. William H. McPheeters, the oldest physician in St. Louis, died at his home in that city on March 15 at the age of 89 years. Dr. McPheeters was born in Augusta County, Virginia, and was educated in North Carolina and Philadelphia. He graduated from the University of Pennsylvania in 1840. After serving in the hospitals of Philadelphia for a year he went to St. Louis, and remained in that city continuously until his death. During the Civil War he was chief of the medical staff of General Sterling Price's Confederate Army Corps. In 1843 he was chosen professor of clinical medicine and pathological anatomy in the St. Louis Medical College, and in 1844 became an associate editor of the St. Louis *Medical and Surgical Journal.* During the cholera epidemic in 1849 he remained in the city and took an active part in the care of cholera victims and in efforts to destroy the plague. Later he published an exhaustive and valuable review of that epidemic. He was one of the founders of the Missouri State Medical Association.

Dr. George W. Edison of Quincy, Ill., died March 10, after a long illness, at the age of 88 years. He was born in Vienna, Ontario, and was graduated from the Medical Department of Toronto University in the class of 1844. He removed to Quincy in 1859. During the war he was surgeon on the Mississippi River hospital boats plying between Vicksburg and St. Louis.

Dr. JOHN A. GREGG of Somerville, Mass., died March 14 at the Massachusetts General Hospital, Boston, of disease of the heart, at the age of 56 years. He was born in Boston, and was graduated from the Dartmouth Medical School in 1883.

Dr. HERBERT ELLIS, senior house surgeon at the Good Samaritan Hospital, Cincinnati, died March 11, following an operation for appendicitis. He was 27 years old, and was graduated from the Medical College of Ohio in 1904.

Dr. HUGO KOETHE of Brooklyn died on March 16 of disease of the heart at the age of 53 years. He was a graduate of medicine of the University of Erlangen in 1874.

Dr. FELIX C. W. PRINTZ died at his home in St. Louis on March 10. He was graduated from the Medical Department of Washington University of St. Louis in 1898, and was instructor in diseases of the nose and throat in that institution. He was a member of the Medical Society of the City Hospital Alumni and the Physicians' Club of St. Louis.

Dr. L. F. CHAFFIN of San Antonio, Texas, died in Austin on March 5 at the age of 64 years. He was born in Tennessee and went to Texas with his parents when five years old. During the war he served as medical officer with the Eleventh Texas Cavalry.

Dr. JOSHUA LARENDON died at his home in Houston, Texas., on March 6 at the age of 66 years. He was born in Charleston, S. C., and went to Texas upon graduating from the Medical College of the State of South Carolina in 1861. During the war he served as medical officer in the Confederate Army.

Dr. J. H. FLEETWOOD of Thibodaux, La., died on March 7, of pneumonia, at the age of 75 years. He was born in Tennessee and was graduated from the Medical Department of Tulane University in 1872.

Rear Admiral GEORGE ADAMS BRIGHT, U. S. N., retired, a surgeon in the Civil War, later a medical director and at one time head of the Navy Hospital, died on March 17, at the age of 67 years, at the Garfield Hospital, Washington. He was born in Bangor, Me., and was graduated from the Medical Department of Bowdoin College.

Dr. G. E. KEENE died at Providence, R. I., March 13, at the age of 52 years. He graduated from Brown University in 1875 and from Harvard Medical School in 1879, after which he served in the Boston City Hospital for eighteen years. He was one of the Rhode Island Hospital staff for six years, when he became superintendent of the State institution at Cranston.

Dr. A. W. SCOFIELD, a well-known physician of Dayton, Ky., suffered a stroke of apoplexy while on his way to see a patient, and died a short time afterward. He had practised medicine in Dayton and vicinity for twenty-five years. He was a graduate of the Medical College of Ohio in the class of 1873.

Dr. WORTHINGTON W. MYERS died at Philadelphia on March 11, at the age of 60 years. He was graduated from the Maryland University Medical College, and entered the United States Navy at the outbreak of the Civil War. He was for twelve years medical inspector of the Philadelphia Board of Health.

Dr. WM. T. DUNLAP of Cincinnati died March 16, of chronic nephritis, at the age of 56 years. He was a graduate of the Cincinnati College of Medicine and Surgery, in the class of 1868.

Dr. BENJAMIN C. LENOIR died at Loudon, Tenn., of pneumonia, on March 14, at the age of 84 years. He was a graduate of the Jefferson Medical College in the class of 1846. Dr. Lenoir was of a distinguished East Tennessee family and had practised medicine in that section for over half a century.

Dr. ALLEN FOWLER of Union City, Tenn., died on March 11, after a short illness. He was a graduate of the Medical Department of the University of Tennessee in 1891.

Dr. EDWIN J. HOWE of Newark, N. J., died suddenly on March 14, at the age of 55 years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1873.

Correspondence.

THE COUNSEL OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: Will you kindly allow me to say in your columns that it is some years since I ceased to be the counsel of the Medical Society of the County of New York and of the New York State Medical Association, and that I have no connection with the case of the People *v.* Conrad, reported in the *Law Journal* of March 17, or with another similar case recently reported in the lay press.

Hitherto I have corrected privately, as occasion arose, a persistent impression in some minds that I am still the County Society's legal adviser; nevertheless I find the conduct of the Conrad case attributed to me, notwithstanding the court's explicit mention by name of Mr. Andrews, the County Society's present efficient counsel, as the attorney who arranged that prosecution. It seems, therefore, advisable, in fairness both to him and to me, to make this correction publicly.

During the period of my retainer the County Society enforced only the provisions of the Public Health Law forbidding medical practice to the ignorant and unqualified, and did not undertake to prosecute violations of the general criminal law by medical practitioners.

W. A. PURRINGTON.

59 WALL STREET, March 21, 1905.

OUR LONDON LETTER.

(From Our Special Correspondent.)

AFTER APPENDICITIS—BLOOD GLANDS—STIGMATA IN EPILEPSY—SIR W. J. COLLINS ON MICROBES AND SANITATION—CONVALESCENTS' INSTITUTIONS—ORTHOPEDIC HOSPITAL—WATERLOO HOSPITAL—THE JUBILEE HOSPITAL AGAIN—A DENTIST'S CLAIM.

London, March 3, 1905.

A FULL dress discussion at the Royal Medical and Chirurgical Society was opened on Tuesday by Sir Frederic Treves, the subject being the subsequent course and later history of cases operated on for appendicitis. He discussed it under two heads: (1) imperfect relief or imperfect recovery after operation; (2) complications attending operation, which may be regarded as accidental or independent of the direct surgical result. He based his remarks chiefly on his private cases, but supplemented his records by statistics of the London Hospital prepared for him by Mr. Hugh Lett. These latter cover a consecutive period and embrace 1,000 cases, and Mr. Lett has not only transcribed notes of these, but has written 797 letters to discharged patients in order to complete after histories. Sir F. Treves said he believed these would form the most important contribution to the statistics of the disease which has yet been made. All operators may therefore be expected to study them and they are too extensive to detail in a letter. Among imperfect results after removal of the appendix in the quiescent period, Sir Frederic enumerated and commented on appendix imperfectly removed (two cases), ovarian complication (nine), persisting or relapsing colitis (eight), persistent local pain (seven), neurasthenia or hypochondriasis (five), continued attacks (nine). Of these last, three were traced to gall stones, two to colic, two to moveable kidney, and one to stone in kidney. There were also five cases in which a tender mass was found in the right iliac fossa; of these, one was inflammatory thickening, three were due to impacted feces, and the other to tuberculous glands. These cases therefore amount to forty-five. The other class, those following the evacuation of a perityphlitic abscess, contained one hundred cases; of these, 40 per cent. were due to persistent sinuses, 24 per cent. to recurrent abscesses, 16 per cent. to recurrent attacks of

appendicitis, 12 per cent. to fecal fistulæ, and 8 per cent. to inflammatory deposits in the right iliac fossa. In this series perhaps the most interesting point relates to the fecal fistulæ, concerning which Sir F. Treves holds that (1) while it remains another attack of appendicitis is exceedingly uncommon; (2) the fistula, unless due to cutting or tearing, has a tendency to close spontaneously, though it may take many months to do so; (3) that fistulæ which appear some days after operation do better than those evident at the time; and (4) a still diseased appendix or a retained concretion is often the cause of the persistence of the fistula. A very important question as to these abscess cases is whether, when they have been simply evacuated, the appendix should be removed in a quiescent period. Many surgeons, among them Mr. Battle, favor a second operation. But it appears that 83 per cent. of the cases have no further trouble, and although the second operation is often easy, it is often both difficult and dangerous. Sir F. Treves does not consider the risk justifiable unless trouble is experienced, when he would remove the appendix. Among the complications, thrombosis of the left femoral vein was met in twelve cases. Why the left should be thus affected is not easily explained. The right thigh is kept at rest, but the left is much used in the necessary movements of the patient in bed.

Sir Wm. Broadbent was to follow, but he recognized the purely surgical nature of the discussion and contented himself with remarking that he seldom heard of the patient after the surgeon had been called in, and rather congratulated himself that when unpleasant results followed the patient usually returned to the operator.

Mr. C. J. Symonds, in seventy-two private cases, had had one of femoral thrombosis (left), one of cardiac embolism, one of non-fatal pulmonary infection, and one of pelvic abscess. Of the seventy-two patients, seventy-one were now in good health. In fifty hospital cases he had traced four with after trouble; two of them having pain in the right fossa, and two being renal. He had not met with thrombosis and was inclined to attribute the exemption to the fact that he encouraged sitting up and movement of the legs at a rather early stage. In acute cases, if the patient was septic, the appendix must be removed or the infection would remain. In the absence of septicemia it was best to lay open and drain the abscess.

Sir T. Lauder Brunton said sometimes a patient returned to the physician suffering from a colitis which had existed before the operation.

Mr. Pearce Gould had had 300 cases. He knew that it was not seldom difficult to remove the appendix, but he also knew the sad results that might follow imperfect removal. As to abscess, only 10 per cent. had any recurrence after drainage, and, therefore, it was wise to wait before undertaking a further operation, until symptoms demanded it. If a surgeon was not called in until suppuration had taken place in acute appendicitis a serious reflection rested on those in charge. The mortality of 27 per cent. in abscess and peritonitis would be reduced to 2 per cent. by early operation. An abscess ought not to be allowed to develop about a diseased appendix.

At this point the discussion was adjourned.

At the last meeting of the Pathological Society, Dr. Arnold Lorand read a communication on "Blood Glands as Factors in the Production of Diabetes and Obesity." He has discovered that after extirpation of the pancreas in dogs, the thyroid shows an abnormal amount of colloid in its spaces, and sugar appears in the urine. If then the thyroid is also removed there is no sugar. The dogs thus deprived of both pancreas and thyroid only survived the second operation three or four days. Dr. Lorand, therefore, thought the functions of pancreas and thyroid were interdependent. The internal secretion of the pancreas is probably produced by the Langerhans islets, which resemble the parathyroids, the medullary part of the adrenals and the interstitial cells of the testicles. The secretion of the islets is probably controlled by a nervous mechanism, which may account for cases of diabetes without pathological appearances in the pancreas. Degeneration of the pancreas has been met with in cases of Graves's disease and acromegaly with glycosuria. Degeneration of the thyroid produces obesity, as does removal of the sexual glands. Atrophy of the pituitary may also be followed by obesity without acromegaly. Obesity from changes in the blood glands differs from that due to overfeeding; in the former glycosuria is rare, but in the latter frequent. In twenty cases of diabetes serum from thyroidectomized sheep had been beneficial. Dr. Pavy referred to three cases of diabetes associated with myxedema in children, but he had not himself met with such a case. His experiments tended to show that pancreatic internal secretion increased the assimilation of carbohydrates and that in healthy animals sugar passed through the circulation in a combined form. Dr. Lorand replied that the Philadelphia cases were not conclusive, the age of the patients was a suspicious point, and they had been treated with thyroid extract.

Dr. Alden Turner communicated to the Medico-Chirurgical Society, on February 14, the result of a statistical investigation as to whether the structural stigmata of degeneration exercised an influence on the progress of epilepsy. He referred to stigmata as structural deviations from the normal arising during the period of visceral and brain growth in the subjects of hereditary predisposition to degeneration. From an examination of 1,000 cases in the epileptic colony he concluded that there was no association between the degrees of mental impairment and the presence of neuropathic stigmata, a fact which favored the view that the interparoxysmal mental condition was really a part of the disease. Dr. Bond said his statistics supported those brought forward and suggested that grouping in age periods would render them more valuable. Mr. Stephen Paget thought some of the stigmata were almost universal among London poor. Dr. Shuttleworth said a single stigma was of no importance, but two or three afforded evidence of degeneration. Hutchinson found facial asymmetry particularly common among the upper classes.

"The Man *vs.* the Microbe" was the title of a lecture given last week by Sir Wm. Job Collins, M.D., at the Polytechnic Health Society, Professor MacFadyen presiding. Taking Queen Victoria's reign as the era of sanitary reform, Sir W. Collins referred to the work of Sir E. Chadwick, who might be called the father of sanitary science, and who had the powerful support of Dr. Southwood Smith and Jeremy Bentham. He then contrasted their views with those of the bacteriologists who hold that specific germs are the source of certain diseases which sanitarians formerly and some now attribute to unhealthy conditions of life, overcrowding and filthy surroundings. Sir William displayed a distinct leaning to the latter view, which might have been expected from his antecedents. He quoted the fact that in the model dwellings of the County Council the death rate is only 10 per 1,000, whereas in the slums which they have replaced it was 40 per 1,000. He quoted Lister, Koch, Virchow, and others, and advised medical men to take broad views, as the tendency of some was to attach too much importance to microbes and germs and too little to predisposing causes and the soil into which the microbe intruded. The hopes, he added, of the advocates of protective inoculations in the lower animals had not been fulfilled, as the Board of Agriculture's Report proved that sheep inoculated against anthrax had succumbed to the disease. Sanitation was not pushed off by bacteriology, but had come to stay. Cleanliness, healthy dwellings, pure water, and fresh air were the best means of preventing disease, it neutralizing the action of injurious germs.

It was decided yesterday at a conference of delegates of the chief convalescent institution to form a central association, in touch with the hospitals and homes, in order to coordinate the work, to effect such changes as may be necessary in consequence of the advances in medicine and surgery and to promote economy and efficiency. Sir W. Church pointed out that at present all convalescents were treated alike and supposed to look after themselves, whereas special treatment and special diet were necessary for the various cases. Mr. Tweedy, Sir Thomas Smith, Sir D. Powell, and Dr. Fowler were among the speakers supporting the proposal. The Earl of Lytton, as chairman of the proposed Home of Recovery, which I announced a fortnight ago as about to be established, heartily supported this movement, and said his committee was endeavoring to raise an endowment fund which could be applied to existing institutions.

At the annual meeting of the National Orthopedic Hospital, it was stated that, in consequence of the amalgamation now nearly completed, the surgical staff was increased from four to six, and a new operating room had been provided to meet the increased work. The amalgamation with the Royal will involve other changes. The hospital now is unquestionably the chief of its kind in this country.

The Duchess of Albany presided at a reception at the Waterloo Hospital for Women and Children, on Tuesday. The Archbishop of Canterbury made an earnest appeal for funds, for the need he declared to be huge, and the surroundings exactly of the sort in which those needs were most certain to be felt. The Duchess said the hospital afforded an unlimited field for kindly thought, energetic work, and liberal donations.

The "Queen's Jubilee Hospital" is again in trouble, if, indeed, its short career can have been at any period described as other than such. A week ago we were told that all the staff had resigned in a body as a protest against the mismanagement, etc. Yesterday the committee stated that all the vacancies have been filled, which looks as if the committee were prepared with a list in case the staff actually resigned, and which seems to show that there are men in the profession who will take any appointment under any circumstances. The affair should interest the King's Fund.

The "glorious uncertainty of the law" has been illustrated in a dentist's claim being bandied backwards and forwards between the courts. The dentist sued a patient for £45 for "bridge work," advice, etc. He was unregistered, and, therefore, at the time could not sue for dental operations or advice, but has since become registered. Meantime, £20 had been paid on account, and he claimed that he could appropriate this to the services for which he could not recover at law, and could sue for the remainder as material supplied (gold, etc.). The lawyers seem to have been more interested in the question of appropriation than the right to practise. At last the Appeal Court has decided that the dentist could elect to appropriate the sum paid to any part of his claim he pleased. So here is a person avowedly incapable of suing as a dentist, unregistered under the act, permitted to recover for the material he used in carrying on unlawful practice. The result seems to support Sam Weller's opinion of the law.

OUR PARIS LETTER.

(From Our Special Correspondent.)

APPARATUS FOR THE ADMINISTRATION OF CHLOROFORM—EULOGY ON PANAS—KNIFE WOUND OF THE RIGHT VENTRICLE, SUTURE, RECOVERY—EMPLOYMENT OF SCOPOLAMINE AS A GENERAL ANESTHETIC IN SURGERY—CONFERENCES CONCERNING NURSLINGS—TREATMENT OF DERMATOSES BY RADIUM—IMMEDIATE EFFECTS OF DECAPSULATION OF THE KIDNEY IN NEPHRITIS—NOMINATION OF PROFESSOR SEGOND TO THE FACULTÉ DE MÉDECINE.

PARIS, February 28, 1905.

At the Academy of Medicine, the question of apparatus for the administration of chloroform, and especially for the simultaneous administration of chloroform and oxygen, is receiving much attention. Lucas-Championnière advocates the use of the Roth-Guglieminetti apparatus, which presents the advantage over other apparatus of not yielding a constant and fixed mixture of air and chloroform. The dose employed may be modified at any instant of the process. Besides, the addition of oxygen to the mixture seems to be an important step in the improvement of the method. It is to this combination of qualities that the happy results attending the use of this apparatus are attributed. Reynier objects to the preceding apparatus because the mixture that it holds is not made up of definite volumes of the constituents. He showed an apparatus constructed according to the ideas of Dupont and his followers, which was so arranged that its mixture was made up of definite proportions. This apparatus has given him excellent results.

The Société de Chirurgie has held its annual session. Professor Segond, the general secretary of the surgical society, delivered a eulogy on Professor Panas, who died two years ago. In this discourse, Segond reviewed the scientific work of this learned ophthalmologist, indicating the important position which Panas occupied as well in general surgery, as in ophthalmology, properly speaking.

The study of various pieces of apparatus for the administration of chloroform filled up the programme of several sessions, and from the discussions which took place, it was concluded that the administration of chloroform by means of the simple compress ought to be definitely and completely abandoned. Among apparatus the most highly praised, we mention that of Roth-Dreger-Guglieminetti, which is characterized by the fact that the patient breathes a mixture of oxygen and chloroform in constantly varying proportions. Of other pieces of apparatus, more simple, and easier of management, were those of Reynier and Ricard. In the latter the patient inspires a mixture of ordinary air and chloroform vapor. The fundamental principle of Ricard's apparatus is the same as that of the apparatus for "carburation." In the bottom of the vessel is the chloroform which gives out its vapors. These vapors are breathed by the patient, and, according to the necessity of the moment, they are mixed with air in definitely increasing or decreasing proportions.

Professor Delorme presented to the society an interesting observation by Riche, a hospital surgeon. The patient was a young woman pregnant four months, who had received a knife wound in the region of the heart. The blade had penetrated the right ventricle. Riche was at the hospital when the woman was brought in about two hours after the accident. He sutured the wound in the heart, and the patient recovered, after having passed through serious complications, such as pericarditis, pleurisy, and generalized bronchial catarrh.

Professor Terrier read a report on the work of Desjardins on the employment of scopolamine as a general anesthetic in surgery. Scopolamine is extracted from Scopolia japonica. It is in the form of prismatic crystals, fusible at 59° C. It changes rapidly in the air and in light, and is most often used in the form of a salt, the bromhydrate of scopolamine. Anesthesia is produced by its subcutaneous injections, made by an ordinary Pravaz syringe. The first injection is made four hours before the operation; a second, two hours before; and a third, one hour before. After the third injection, sleep is complete, as a rule. The duration of sleep varies between four and five hours; besides this, a remarkable fact is that the anesthesia persists, when the cerebral functions have become intact. The patients generally come to without the slightest malaise; they can drink and even eat soon after waking. The great advantage of scopolamine over the other anesthetics is its harmlessness. Two inconveniences are noted, however, in this method of general anesthesia; first, the inconstancy of action of the anesthetic according to the patient, the case, and the product used. Again, there is the vasodilatation, which, for certain operations, necessitates detailed precautions in the way of hemostasis.

At the Société de l'Internat, Professor Budin gave a very interesting talk on the conference of nurslings. He pointed out the importance of the question of the establishment of these conferences, as much from the point of view of social hygiene, as from the point of view of the increase of population. It has been well proved that in the first two years of life the principal cause of death is gastrointestinal troubles of the infant. The chief object of these conferences is to give to mothers good and useful medical advice, to teach them the extreme value of breast feeding, and to give them useful advice about the sterilization of milk, about the care of the nipples, and the quantity of milk. According to Budin, the quantity of milk suitable to give, according to the age and the weight of the infant, is 100 gm. of milk to 1 kilo. of weight of the infant. The happiest results have followed the holding of such conferences, and in every village in which they have been instituted, infantile mortality has decreased in goodly proportions.

Replacing Professor Tillaux, deceased, Professor Paul Segond has been nominated to the chair of operative medicine. The well-known works of Segond on gynecology have made him worthy of this honorary title, and the Faculté de Médecine de Paris is happy to count among its members a man as active, a surgeon so distinguished, a spirit so liberal.

At the Société Médicale des Hôpitaux, Danlos spoke concerning the treatment of dermatoses by radium. He concludes from his personal researches that up to the present, radium has shown a true therapeutic action only in three affections; lupus vulgaris, pearly epitheliomata, and vascular nevi. The action of radium appears to be practically inferior to that of the x-rays. The great therapeutic value of radium is shown, however, when it comes to the treatment of cavities inaccessible to the Röntgen rays.

Henri Claude and Pierre Duval have studied the immediate effects of the decapsulation of the kidney in nephritis. They conclude that the decapsulation of one kidney only is sufficient to determine a notable increase of elimination, and a lowering of arterial pressure. The decapsulation appears to be especially indicated in subjects afflicted with chronic sclerosing nephritis, whose kidneys are relatively permeable, but which may become insufficient under the influence of acute congestive attacks.

THE PHYSICIAN'S AIM.

To the Editor of the Medical Record:

Sir: All the new forms of quackery—and their name is legion—begin and end their propaganda with an attack upon the medical profession. From these and other sources medical men are constantly subjected to misrepresentation and abuse. Physicians do not usually care to reply to attacks of this character, and as a result, the laity has either a dim or a distorted conception of the principles that control in the practice of medicine. As a silent educator, I have hung in my reception room the following brief statement of the ethics and ideals of the medical profession. It is entitled "The Physician's Aim":

"To be accurate in diagnosis and painstaking in prescribing; to allow no prejudice nor theory to interfere with the relief of human suffering and the saving of human life; to lay under contribution every source of information, be it humble or exalted, that can be made useful in the cure of disease; to be kind to the poor, sympathetic with the sick, ethical toward medical colleagues, and courteous toward all men; to regard his calling as that of one anointed to holy office, firmly convinced that no nobler work can be given to man, and to go forth to his labor with love for humanity, inspired with a reverent assurance that for this cause came he into the world."

Charles J. Douglas, M.D.

321 Center St., Dorchester, Mass.

Progress of Medical Science.

New York Medical Journal, March 18, 1905.

A Case of Acute Turpentine Poisoning.—The patient of G. Hausser was a man of thirty-seven years, who in order to rid himself of a tapeworm, took upon his own initiative one tablespoonful each of spirits of turpentine and castor oil every 3 hours, taking in all from four to five ounces. Severe abdominal pain and bloody stools led him to seek medical advice. He was stupid, dizzy, with unsteady gait, flushed face, dilated pupils, no fever, tender abdomen and frequent and painful mictrition. Urine showed red and white blood cells, bloody hyaline and granular casts and renal epithelium. Was ordered flaxseed tea and enemata of the same, with milk, barley water and eggnogg. Next day a slight cystitis had developed which soon yielded to tincture of belladonna and acetate of potash. By the fourteenth day all symptoms had disappeared and his condition was apparently normal. The tapeworm was not completely expelled and new segments were passed some weeks later. A dose of lannate of pelletierine effected its complete removal.

The After Treatment of Abdominal Sections with Eserine Salicylate.—The dose of this remedy recommended by D. H. Craig is one-sixtieth of a grain, repeated if necessary, but if the patient has previously suffered from chronic constipation the dose may be doubled or even trebled. The remedy should never be given except in connection with atropine which antagonizes all the former's undesirable effects. The time of its administration is of prime importance. The atropine should always be given, as it is so commonly used by surgeons generally, before the anesthesia, first, because its action is slower than that of eserine, and, secondly, because when so used it gives great aid to the anesthetist in doing away with most if not all of the excessive pharyngeal secretion excited by the first inhalations of the ether. Craig gives the atropine in a dose of one one-hundredth of a grain by the mouth, one hour before anesthesia when there is time, otherwise one-one-hundred and fiftieth of a grain subcutaneously immediately before. The object of the medication is to prevent intestinal paresis. The salicylate is the only reliable salt to employ. The solution should be freshly made. Many of the stock tablets as purchased in the open market have proven inert. Under the influence of the eserine the patient is comfortable. Morphine has been very rarely needed or even desired, except for distinctly extraabdominal pain, but when so demanded either morphine or codeine can be given with greater freedom than without the eserine as there is less danger of obnoxious constipation following its use.

Medical News, March 18, 1905.

The Importance of the Physical Examination of the Back in General Diagnosis.—J. P. Arnold believes that examination of the back is much neglected. Many disorders present marked indications found by inspection of the spine in the region supplied by the posterior primary divisions of the spinal nerves, corresponding to those segments of the cord from which the parts affected derive their innervation. In chronic diseases there is usually evident in the areas referred to a deficient vascular tone. In cases of disturbed stomach function, indications will be found by an examination of the back between the fourth and tenth dorsal segments of the spinal cord; and in cases of chronic constipation, accompanied as they are most frequently, by disturbances of the functions of the stomach, additional indications will be found in the lower dorsal, lumbar and sometimes in the sacral regions of the cord. This class of cases is simply quoted as an example of what may be found in an examination of the back, and is applicable to all of the diseases acute or chronic, which come under the observation of the physician, varying only in the localization along the vertebral column which corresponds to the disturbed part. These indications are marked by slight lateral deviations of the spinous processes, atrophied erector spinæ muscles, irregularly contracted bundles of muscle fiber, which are nearly always tender to the touch when rolled under the palpating finger, and relaxed interspinous ligaments indicated by prominence or depression of one or more spinous processes. As these indications are always found in the region of the posterior primary divisions of the spinal nerves which arise from the segment of the cord which supply the organ or part affected, it seems logical to assume that they are indications of disturbances of the functional activity of those segments, and this assumption is borne out by our more recent knowledge of the functions of the spinal cord. The remainder of the paper is devoted to a brief description of the nervous mechanisms of the different parts of the body and the segments of the cord from which they arise.

Local Anesthesia by Cataphoresis and by Mechanical Pressure.—W. J. Morton gives the history of cataphoresis medication and describes special apparatus he has devised for its employment. It is possible to administer by this method cocaine, eucaine, orthoform, mivanin, chloreton and similar remedies. One operation for removal of a nevus, done under cataphoresic anesthesia is described in full. A favorite combination of remedies is that of cocaine and adrenalin in guaiacol. The term "pressure anesthesia," refers to the forcing of medicated solutions into the tissues by the pressure of vapors and gases or by mechanical pressure. It has been in use for some years by the dentists who have filled a tooth cavity with a cotton pledget dipped in cocaine-guaiacol to which an equal amount of sulphuric ether has been added. The cavity has been immediately covered with a soft rubber filling. In a few minutes the sensitive contents of the cavities have become anesthetized, the evaporating ether forcing the anesthetic into all the tooth recesses. In minor surgery, the same plan may be followed by the substitution of a watch crystal, cupping glass or test tube, over the area to which the anesthetic has been applied.

American Medicine, March 18, 1905.

Cholecystitis as a Complication of Lobar Pneumonia.—J. M. Anders reports three cases. Although an analysis of these cases does not warrant drawing any general conclusions still the clinical observations may serve to direct attention to cholecystitis as a complication in rare cases of lobar pneumonia. The local symptoms and physical signs are characteristic, but the type of the condition is not severe. It is to a great extent overshadowed by the pneumonic condition. Although no general or constitutional symptoms, distinctive of the lesions, are recognizable, Anders is pretty fairly convinced that the clinical course of pneumonia cases is not, as a rule, materially modified by the complications of catarrhal cholecystitis except in cases in which chronic hepatic disease existed previously, when the toxemic symtoms may be intensified by the development of an acute, widespread cholangitis and cholecystitis. Two of the cases terminated in recovery but Anders states this result was not due to any special method of treatment, as attention was mainly bestowed upon the serious primary affection. A mild saline laxative was employed in one of the cases and small doses of mild mercuric chloride in the other. In the case which terminated fatally, nothing but the general treatment of the pneumonia was carried out, because the grave pneumonic features and the cardiac and pulmonary complications called for active measures.

Primary Tuberculosis of the Female Breast.—G. W. Spencer reports the case of a woman aged 20, in whom the entire breast was amputated, together with the axillary glands, fat, and fascia. Pathologic and microscopic examination of the mass showed tuberculosis of the breast with associated involvement of neighboring lymph-nodes. There were no tuberculous foci in other parts of her body. Spencer concludes radical operation is indicated in every case of unquestionable tuberculosis of the breast. The breast, together with the skin overlying the tuberculoma, the glands, fat, and fascia from the axilla, should all be removed as one piece. This appears the safest way to prevent recurrence and dissemination. Such was his procedure and thus far it has proved most satisfactory in every respect.

Surgical Treatment of Bright's Disease.—W. Hershey Thomas, after a thorough review of the literature, concludes that with two exceptions (nephrotomy for renal calculi and the drainage of abscess, and nephrectomy for the excision of renal tumors), renal decapsulation is preferable to all other surgical proceedings upon the kidney for the following reasons: (1) No damage is done to the important secreting structures; (2) there is less danger of hemorrhage, and (3) other things being equal, it should be preferred on account of the greater simplicity of wound treatment.

Calcium Chloride in Postoperative Nasal Hemorrhage.—Reynold Webb Wilcox reports a striking example of the brilliant results from the use of what Wright has designated the "physiologic styptic" in a case of incontrollable hemorrhage. Although the physiological demonstration was made in 1894 it has attracted but little attention in this country. The author endorses the results of laboratory experimentation that calcium chloride increases the fibrin in the blood and its coagulability.

The Journal of the American Medical Association, March 18, 1905.

Harelip and Cleft Palate.—G. V. I. Brown, after a classification and description of the varieties of these defects, condemns the radical operation in the young infant on account of the high death rate, the danger of meningitis, the unsatisfactory cosmetic results at that age, the risk of too great approximation of the turbinates, occluding the nasal passage and producing mouth breathing, etc. If conditions are favorable he would use adjusted strips to prevent the action of the lower jaw from forcing the maxillary bones

apart and to cause an opposite effect when the child laughs or cries. Of course the child should be mouth fed; the sucking habit should be overcome. The proper age is after the full eruption of the deciduous teeth and before the speech habit has been fully acquired. He would then use a screw appliance, which is illustrated, to approximate the bones and would also use proper treatment for the diseased oral surfaces. In young patients this will probably be sufficient, in older patients some crushing operation may be required. It is most desirable to bring the anterior portions into direct contact so as to allow freshening, not only of the soft borders, but the bony tissues as well, thus securing complete circulation to nourish the flaps when the final mucoperiosteal operation is performed. He emphasizes the importance of having needles selected with curves suiting each part of the operation. The fuller details of the technic of his method are left for a future article. The importance of after-treatment is especially dwelt on, and he particularly mentions singing as one of the best practical aids to speech improvement. The patients are often neurotic and the complicating neuroses must be considered in the treatment. With his method he thinks the restoration of the palate in its nearly perfect form can be obtained. The difficulties of oral asepsis are noticed, and he says his postoperative sheet anchor for the mechanical cleansing of the parts is dioxygen, which, with a 2½ per cent. of carbolic acid solution, should be used alternately each hour during the day and at least four times at night. For this he uses a hospital syringe and injects with force enough to dislodge little particles of débris, but not enough to do injury. Wiping with cotton wool applicators is required also three or four times a day, and nebulizing some of the oil preparations are used as supplementary after the washings throughout the course of treatment.

Alcoholic Borderline Psychoses.—F. P. Norbury gives the history of two cases of alcoholic mental derangement; one of typical alcoholic delusions of infidelity following the stoppage of alcohol in a steady drinker, and the other of acute alcoholic maniacal attacks following excesses. Both cases are discussed at some length. His conclusions seem to apply more particularly to the latter type, which he considers as properly classed among the minor psychoses of alcoholism. He says that from an experience with several hundred such cases, including the polyneuritic psychoses marked by amnesia, paramnesia and confusion, with marked hallucinations, he has been led to the following conclusions regarding these mental disorders: (1) They are rare in acute alcoholism, but may appear in adolescents of neurotic type. (2) They are more frequent after adolescence and up to 40 or 45 years of age. (3) They occur both in continuous drinkers and in periodic delinquents. (4) The prognosis is variable, depending on inherited frailties and on moral development. (5) Early treatment is advisable as a prevention of major psychoses. (6) Treatment is successful in the majority of cases, providing the physician has the earnest co-operation of the patient and can have him under his care for a protracted period. (7) Such cases should be distinguished from ordinary chronic alcoholism and should be treated from the standpoint of mental disease.

The Blood Changes in Pneumonia.—In blood cultures from 175 cases of lobar pneumonia, E. C. Rosenow found pneumococci in all but 15. In eleven of the fifteen cases the second culture was not possible. In the other four, repeated cultures failed, though in one careful search of the smears directly from the blood revealed pneumococci. Leucocytosis was high in all four, and he was inclined at first to suspect a phagocytic action, but later research showed that the negative cultures were made later in the disease, thus indicating a diminution in numer or viability, or both, of the pneumococci at the time of crisis. Rosenow does not seem to consider the blood cultures of great prognostic value in this disease, though he says, other things being equal, a high leucocytosis appears to be a favorable sign rather than otherwise. The agglutination test of the pneumococci he does not think of much practical value. The point he considers of most importance is the reaction changes; a well-marked acid reaction, associated with a voluminous sediment appearing in cultures of pneumococci in pneumonic and not in normal serum. He asks, in view of this fact, whether some of the symptoms of pneumonia may not be due to an acid intoxication of the system, and, in support of this theory, he adduces experiments which have been made with the alkaline treatment for a year past in Dr. Frank Billings' clinic, in the Presbyterian Hospital. From one to three drams of sodium bicarbonate in at least four ounces of water, were given by the mouth or in still larger doses by the rectum. No other treatment was employed except heart tonics, catharsis or venesection whenever required, which was seldom. Judging from the results this alkaline treatment seems rational.

Laryngeal Papillomata in a Child.—L. D. Brose reports the successful removal of papillomatous laryngeal growths from two children, aged 11 years and 19 months, respectively. The diagnosis of these conditions is easy if laryngoscopic view is possible. Otherwise the vocal and respiratory disturbances, aphonia or altered voice, difficulty of breathing, especially during sleep, etc., will have to be relied on. If the patient is old enough to co-operate with the physician and an endolaryngeal operation is possible, life can generally be saved and the voice restored, but recurrence is to be expected in 25 to 50 per cent. of the cases. When an endolaryngeal operation cannot be successfully done the only recourse is in external laryngotomy, preferably after tracheotomy. Thyrotomy in a child is tedious and difficult, and the mortality is high when done for papilloma.

The Lancet, March 4, 1905.

The Treatment of Severe Curvatures in the Tibia by Means of Manual Osteoclasis.—Personal experience in 30 cases is detailed by T. H. Openshaw, who illustrates his method by clinical history of one case with photographs and *x*-ray pictures. He regards the operation as far superior to cuneiform osteotomy for the following reasons: In the first place the bone is broken exactly at the spot and along the plane which is absolutely the proper one in order to allow the bone to become straight. It is impossible precisely to ascertain where this plane is situated until the bone has been broken. It is only by straightening the bone and allowing it to break that the proper line of fracture can be determined. Every operator knows how difficult it is to remove by cuneiform osteotomy exactly the proper-sized wedge, and to remove it from exactly the correct plane in the bone. Secondly, the bone is lengthened instead of being shortened by the excision of a wedge-shaped portion. Thirdly, instead of an open wound with much damaged bone and periosteum a simple intraperiosteal greenstick fracture is produced, which is firmly healed and allows the child to walk in three weeks. Finally, the operation can be performed and the child treated as an out-patient. He believes, also, that the tibia must be actually broken in order to insure a straight limb. The operation is applicable to any case in a patient not over ten years of age.

The Cause of Pain in Cases of Gastric Ulcer and its Bearing on the Operation of Gastro-Jejunostomy.—According to C. W. Mansell-Moullin, the pain in gastric ulcer is not due to mere contact of food with the mucous surface of the organ, but to the movements of the stomach affecting the sensory nerves distributed around it. Sensory nerves derived from the intercostals are distributed in abundance in the parietal peritoneum, or rather in the subserous cellular tissue underlying it. The least drag upon this is instantly resented. The painless ulcer that forms almost without a symptom and suddenly ruptures into the general peritoneal cavity is nearly always situated on the anterior surface far away from the parietal peritoneum and the sensory nerves. The ulcer that causes the most suffering is either on the lesser curvature or at the pylorus, unless it has already contracted adhesions to the parietal peritoneum elsewhere, so that it can drag upon it directly, and the pain increases as the movements of the stomach become more energetic during digestion and ceases when they do. Whether there are other accessory causes or not, there can be no question that dragging upon the parietal peritoneum as the stomach moves during the process of digestion is the chief source of the pain in cases of dyspepsia and gastric ulcer. What is true of pain in cases of ulcer, is also true of tenderness on deep pressure. All these facts have an important bearing on the success of the operation named in the title. The object here is to drain the stomach and place it at rest. If this can be accomplished the vomiting and pain cease. If the pain continues it means that there is still dragging upon the sensory nerves under the parietal peritoneum around, and that the operation has failed in one important particular. To accomplish this in all cases is no easy matter. If the ulcer is comparatively small, so that it can be excised and merely a thin linear cicatrix left without any puckered bands or adhesions, success is fairly certain. But in the majority of cases, by the time a surgeon is allowed to operate, course after course of medical treatment has been tried, and has failed, and the wall of the stomach has become so far involved that excision of the ulcer means a fairly large gastrectomy. In such cases there is usually no option if gastrojejunostomy is contemplated. The opening in the stomach must be made where it can be. But when there is a choice, the opening should either be made quite at the cardiac end, so that the pyloric portion has no work to do; or if it is made near the pylorus there must be a very free division of the circular muscular fibers, as in the case of simple gastrotomy.

A Case of Acute Intussusception of the Sigmoid Colon Due to a Subserous Polypoid Lipoma; Laparotomy; Excision of Pylorus; Recovery.—The patient of J. H. Ray was a woman of thirty years, who had had abdominal pain in the left lumbar and iliac regions for six months before coming under observation. On one occasion she had severe pain after the bowels moved, and was somewhat collapsed.

An enema given the next day was followed by a violent expulsive effort during which a polypus as large as a medium-sized orange protruded through the anus. This was regarded as the apex of the intussusception, a view, confirmed by operation, which is described in full. The intussusception measured about one foot in length, the neck being over the left sacroiliac synchrondrosis. Reduction was fairly easy. The last part to unfold was at the junction of the middle and outer thirds of the omega loop, and this was brought out of the laparotomy wound and found to contain a tumor that completely blocked the lumen of this part of the colon. The colon having been incised the tumor was exposed and found to be the same mass that had protruded through the anus. The tumor was removed and it was necessary to cut through the wall of the bowel completely to effect removal, thus opening into the mesocolic angle. The wounds in the bowel were sutured with celloidin thread and the abdominal wall was closed in four layers, leaving a small drainage-tube at the lower angle of the wound so as to reach the bottom of the pelvic cavity. The after-treatment was simple and the subsequent progress of the case was uneventful.

British Medical Journal, March 4, 1905.

The Prospects and Vicissitudes of Appendicitis After Operation.—Sir Frederick Treves discusses this subject under two heads: The degree of imperfect relief, or of imperfect recovery after operation; and the complications which may attend operation, and which may be regarded as accidental or independent of the direct surgical results of the case. The writer has records of forty-five cases in which the operation of removing the appendix during the quiescent period, had more or less completely failed. A few of these cases he was directly interested in. The various causes of this condition are classified as follows: In two of the cases, the appendix had been imperfectly removed. Coexisting ovarian trouble existed in nine cases. There is a close anatomical relation between the vermiform appendix and the right ovary, especially in the matter of their lymphatics. Both organs are commonly simultaneously inflamed. The writer believes that it is often almost impossible to distinguish clinically betwewen chronic appendicitis and chronic ovaritis. It is very desirable in operations upon women, to systematically examine the right ovary when the appendix is being removed. Eight patients suffered from colitis. The association of colitis and appendicitis is common. In seven patients there was persistent pain in the right iliac fossa. Five cases were pronounced neurotic or hyperchondriacal. In nine instances, "attacks" were reported to have continued without improvement after the operation. In three the pain was proved later to be due to gall-stones, in two to colic, in two to movable kidney, in one to renal calculus, while in one the cause was not explained. In five cases a tender mass appeared in the right iliac fossa some time after the operation. One instance was simply inflammatory, which condition finally disappeared; in three others the tender lump was a fecal mass, while in the fifth it was due to tuberculous glands. Under the heading of imperfect results after the evacuation of a perityphlitic abscess, the writer tabulates—persistent sinuses, 40 per cent.; recurring abscesses, 24 per cent.; recurring attacks of appendicitis, 16 per cent.; fecal fistula, 12 per cent.; inflammatory deposits in the iliac fossa, 8 per cent. In the London Hospital Series of one thousand consecutive cases, a number of complications appear. There were forty-nine cases of fecal fistula, seventeen of bronchopneumonia, fourteen of pleurisy with effusion, twelve of thrombosis of the femoral vein, ten of intestinal obstruction. Of abscess, there were twelve cases of secondary and eleven cases of residual. There were a few cases of empyema, acute bronchitis, pulmonary embolism, pleurisy without effusion, nonsuppurative parotitis and pylephlebitis. In six of the one thousand cases, the appendicitis was associated with pregnancy. It can be seen from this review that excepting fecal fistula, intestinal obstruction and the persisting or extending abscess, the principal complications are those of septic infection.

Some Peculiarities of Appendicitis in the Female Sex.—George Heaton states that appendicitis is about three times as common in the male as in the female. Although various causes have been assigned to explain this fact, it is more probable that a developmental or anatomical difference is the real cause. Pregnancy does not seem to predispose to a primary attack of appendicitis, but if a patient has previously suffered from this disease, and afterward becomes pregnant, the pregnancy may light up another attack. Pregnancy greatly increases the risks and dangers of appendicitis. The fatality depends partly upon the stage of pregnancy, and partly upon the severity of the attack. The further advanced the pregnancy is, the worse is the prognosis, especially if pus has formed. Suppuration increases the risk of life enormously. According to Abrahams, the mortality of cases of perforative appendicitis even when operated upon with no delay, is as high as 58 per cent., with a mortality of the fetus of 90 per cent. However, mild attacks of appendicitis may occur in the early months of pregnancy and the inflammation completely subside and pregnancy go on uninterruptedly to term. The writer believes that it ought to be an almost invariable rule in cases of pregnancy, to remove the appendix almost as soon as the diagnosis is made. In all cases of appendicitis in married women, it should be ascertained at once whether pregnancy exists, for in such cases the prognosis and treatment will be materially altered. In cases of pregnancy in which miscarriage occurs, careful examination should be made to determine whether appendicitis exists. The writer believes that the appendix is probably responsible for a very large proportion of so-called attacks of right-sided pelvic peritonitis in women. The explanation of the greater frequency of right-sided salpingitis and ovaritis over left-sided affections, is obvious when it is realized that in many cases the inflammation of the tube or ovary is an extensive form of a diseased or disordered appendix. In removing the appendix in women, in cases in which no suppuration is present, it should always be a rule to examine the right uterine appendages before closing the abdomen.

The Relationships Between Colitis and Appendicitis from a Surgical Point of View.—C. B. Lockwood declares that it is not open to doubt that any form of colitis may be associated with appendicitis. He speaks of those cases in which at operation the end of the ileum, the cecum and the right colon are obviously inflamed. Besides, there is tenderness along the right colon and rigidity of the abdominal wall. The relationship here is a mere question of extension by proximity, facilitated perhaps by identity of vascular supply. The bowels soon recover when the appendicitis has ceased. In certain cases, colitis may be the prominent feature so much so that the appendicitis may be obscured and overlooked. It is quite possible that appendicitis may cause coprostasis by interfering in some way with the nervous mechanism of the bowels. In cases of mucous colitis associated with coprostasis, in which there is no evidence of appendicitis, the patients should be examined under an anesthetic. The writer cites two cases in which the diagnosis was difficult, because of absence of pain and tenderness about the site of the appendix. The inflamed appendix was found to be hidden away behind the right colon. After a period of rest in bed, careful dieting, and enemas, the diagnosis became clear. As to mucomembranous colitis, the writer declares that it can cause appendicitis, but he does not know whether appendicitis can cause mucomembranous colitis.

Berliner klinische Wochenscrift, February 27, 1905.

The Value of Neumann's Orcin Test for Sugars in the Urine.—Mann reports on a series of control observations undertaken to determine the reliability of Neumann's recently described orcin reaction. On examining thirty-five diabetic urines, it was found that a positive reaction for dextrine was always obtained, and in three cases in which the sugar had been reduced by diet to such a degree that Nylander's and Trommer's tests and the polariscope gave negative results, it was still possible to obtain a good dextrose reaction with orcin. The test was also found of value for the differentiation of levulose, and one hundred and fifty nondiabetic urines gave negative results except two, in which levulose was shown to be present, once owing to the ingestion of a large amount of raspberry jam, and in the other case owing to unexplained reasons. Albuminous urines give less clear results, and it is always advisable to remove the albumen before applying the test. Urates and phosphates are without influence. The author concludes that the reaction is clinically valuable owing to its delivery and its ability to differentiate a number of sugars by a single test.

The Nature of Hay Fever Toxin and Antitoxin.—Prausnitz says that of 505 patients treated with Dunbar's hay-fever antitoxin pollantin, whose histories had been reported to the Hamburg Hygienic Institute up to the end of 1904, 299 were rendered completely immune by the treatment, while in 143 the cure had been only partial, and in 63 there had been no improvement. Counts of the number of floating pollen grains in the air showed that the occurrence of these particles was exactly in proportion to the rise and fall of the hay fever season. It was found possible to extract the toxin from all the thirty varieties of pollen so far tested by maceration in salt solution, and subsequent precipitation with alcohol, or by dialysation. The substance obtained, termed pollentoxin, gives all the albumin reactions and is so potent that in the case of one patient the application of 1-40,000 mg. to the conjunctiva was sufficient to give rise to a well-marked attack. The methods employed in standardizing the antitoxin obtained by injecting pollen into horses are then described. The essential feature of the process consists in determining the amount of antitoxin which, when added to the toxin, will neutralize it so that no reaction takes place when the mixture is applied to the conjunctiva of a susceptible person.

Observations are also detailed which tend to show that pollentoxin and pollantin represents a true toxin and antitoxin, just as is the case in diphtheria and tetanus.

Münchener medizinische Wochenschrift, February 28, 1905.

The Use of the Esophagoscope in Diagnosing and Removing Foreign Bodies from the Esophagus.—Starck and Reizenstein both discuss this subject and draw conclusions extremely favorable to the method. Starck has collected seventy-three cases in which foreign bodies were successfully removed by the aid of the instrument and only four failures have been reported. He describes a number of his cases in which large pieces of bone, fish bones, etc., were the offending bodies, and sums up his position as follows: Esophagoscopy affords the most reliable diagnostic measure in cases of suspected foreign bodies in the esophagus. The examination may be facilitated by the preliminary use of the *x*-ray and the soft stomach tube. Exact knowledge of the topographical relations of the foreign body is to be obtained only by esophagoscopy. The method should be employed in all cases and as early as possible. Extraction through the instrument is the safest and most satisfactory procedure for removal, and other means, such as attempts to push the object into the stomach, are to be avoided. If extraction through esophagoscopy is not possible either esophagotomy or gastrotomy becomes necessary. Reizenstein describes a number of difficult cases in which artificial teeth plates and bones were impacted, and expresses similar views concerning the utility of the method and emphasizes the importance of resorting to it early, before changes in the mucous membrane have taken place.

Distention of the Esophagus for Removal of a Foreign Body.—Franck, while ship's surgeon, had occasion to treat an arteriosclerotic man of sixty, who had swallowed a large lump of tough meat, which stuck in his gullet and occasioned him severe distress. Attempts to push it down with the stomach tube had to be desisted from owing to the excessive reflex irritability of the patient's throat and the state of his blood-vessels, which rendered the retching caused by the procedure very dangerous, and also owing to the pitching of the boat. Under expectant and palliative treatment the patient's condition grew steadily worse, until on the third day he was exhausted and apathetic, but refused all mechanical means of relief. Believing that by distending the esophagus with gas the obstruction might be forced down, the two halves of a seidlitz powder were administered separately, with directions to retain the gas by holding the mouth and nostrils shut. After a few moments a sudden feeling of relief was experienced by the patient and it was found that the offending mass had been driven into the stomach by the pneumatic pressure.

The Technique of Laparotomy.—Müller has devised an appliance intended to protect laparotomy wounds from infection during the course of the operation, by the hands, drop infection from the breath in speaking, intestinal or tumor contents, purulent exudates, etc. In spite of all possible care it still sometimes happens that clean wounds are infected and the means in use to prevent this are not adequate. The author's device consists of a series of metal spring clips placed every 3 cm. along the length of a sheet of thin rubber tissue, and intended to be slipped over the edges of the incision. By this means the cut surfaces and the skin for a considerable space round about are covered with a sterile layer of rubber which is not in the way, can be readily replaced if soiled and which protects the exposed tissues from mechanical injury as well. The material is made and sold by the meter, so that it is an easy matter to cut off the amount needed for each incision.

Deutsche medizinische Wochenschrift, February 16, 1905.

The Value of Alcohol Dressings.—Brugger commends this form of dressing most highly and advises its more universal application. The affected part is covered with gauze saturated with alcohol and applied in about eight loose layers. Over this comes a thick layer of absorbent cotton, and outside of this some impervious material in which a few holes have been pierced. It is important to make the dressing a generous one which will cover a large, healthy area on either side of the diseased tissues. Salzwedel, the originator of the method, used ninety-six per cent. alcohol, but the author believes that equally good results follow the use of about fifty per cent. alcohol, though below this strength the action is less efficient. The skin should be dry and not macerated before the dressing is applied, otherwise there is danger of caustic action, and open wounds should be protected from immediate contact with the alcohol by packing with sterile gauze. The dressing should be kept moist but not wet, and it is advisable to change it about once in twenty-four hours. The measure gives most gratifying results in all forms of inflammatory conditions of the skin and lymphatics, such as phlegmons, panaritium, furunculosis, lymphangitis, etc., and not only curtails the infection but has a markedly anodyne effect. It is important not to apply the dressing too tightly, and to caution the patients as to the inflammable nature of the alcohol vapor.

The Prophylaxis and Abortive Treatment of Gonorrhea.—Finger discusses these two questions and reaches the conclusion that the methods employed to accomplish the desired results are not satisfactory. So few patients come under observation at a stage when the organisms have not yet penetrated the deeper epithelial layers and are, therefore, still accessible to the action of antiseptics, that the percentage of successfully aborted cases is very small. It is the author's practice even if the case is seen early, to proceed in the systematic way by prescribing injections of some of the non-irritating silver preparations. The cases that would prove successful under the ordinary abortive measures, react well to the routine procedure and are always mild in course. The attempts at prophylaxis by antiseptic injections after connection are condemned by the author, in the first place on account of their unreliability and secondly, because when long continued they give rise to chronic irritative and inflammatory conditions of the urethra, which are almost equal in importance to the lesions following gonorrheal infections.

Enhancing the Agglutinating Power of Typhoid Bacilli.—Sehrwald has found that poorly agglutinating cultures of typhoid bacilli frequently show marked increase in agglutinating power after cultivation on potato or media containing potato juice. On return to potato-free media, the agglutination value drops again. By using bacilli grown on potato or potato-water media it is possible to shorten materially the time necessary for the Widal reaction or for identifying suspected organisms by their agglutination reactions. In growth on potato media the organisms frequently develop in long rods or threads, and this phenomenon, as well as the increase in agglutinating power, seems to depend on the fact that on potato the bacilli suffer a certain amount of impairment of vitality. Similar changes may be observed in paratyphoid and dysentery bacilli after cultivation on potato.

French and Italian Journals.

Milk of Tuberculous Cows.—A considerable part of the milk that is sold day by day, is furnished by tuberculous cows. Even up to the present time it has been declared that there is no danger in the consumption of milk given by tuberculous cows providing the breasts of the animals are not diseased. Moussu reports that he has been able in his experiments to cause tuberculosis in animals by feeding them commercial milk furnished by tuberculous cows whose breasts were not diseased. This investigator believes that this element of danger ought to be eliminated, and proposes a very simple plan. He would oblige the milk dealers not to use any milk but that furnished by animals absolutely healthy and free from tuberculosis.—*Gazette des Hôpitaux Civils et Militaires,* February 16, 1905.

Syphilis Acquired by a Child of Ten Years.—Oltramare reports this case. The child had been sent away from school on account of alopecia and was referred to the writer for treatment. The patient on being examined, was able to describe the manner of the loss of hair. It had fallen out in small, irregular and disseminated patches as in syphilitic alopecia. Further enquiry discovered the fact that there had been former generalized eruptions of papular aspect, while examination of the present condition revealed mucous patches and pigmentation of the neck. The alopecia was a syphilitic manifestation, not diagnosed, by reason of the age of the patient. Oltramare declared, that if in ten or fifteen years this patient presented the symptoms of tabes or of general paralysis, one would be justified in considering them non-specific if the true diagnosis had not been made in so clear a manner.—*La Presse Médicale,* February 8, 1905.

Subcontinuous Pneumonia Complicated by Pernicious Delirium.—Giuseppe Baschieri-Salvadori, under this heading, describes a case of a healthy girl, who has lived for some years in a malarial region near Rome, but had been away from that region in the mountains for eighty days before her attack of sickness. This begun with symptoms of pneumonia; high fever, dyspnea, bloody sputum and signs of consolidation, which lasted only a few days. They then disappeared and were succeeded by a sudden attack of severe delirium, with pain in the head, with a temperature of 96.8°, and a much enlarged spleen. After a deep sleep the patient awoke sane, with a temperature of 100.4°, and a pulse of 120. Cough and bloody expectoration, pain in the chest and râles at various points now recurred. This condition lasted only one day, when the patient appeared entirely well. As no blood examination was made, nor enough quinine given to destroy malarial parasites, had they been present, the author inclines to the belief that the lung symptoms were merely those of a temporary congestion. This condition he names subcontinuous pneumonia.—*Gazzetta Medica di Roma,* January 1, 1905.

Book Reviews.

THE EFFECTS OF TROPICAL LIGHT ON WHITE MEN. By Major CHAS. E. WOODRUFF, A. M., M. D., Surgeon, United States Army. New York: Rebman Company; London: Rebman, Limited, 1905.

THIS is an exceedingly interesting work on a novel subject written by one who, besides having had practical experience as an army surgeon in the Philippines, has evidently given much thought and study to questions of tropical hygiene, and speaks, therefore, with all the authority of an expert. The origin of the work, he tells us, was in an attempt to prove or disprove von Schmaedel's theory that the skin pigmentation of man served to exclude the short or actinic rays of light whose action is to destroy living protoplasm. If this theory is true it will explain at once many anthropoligical riddles. We find in it a reason why Europeans, at least northern Europeans, while capital colonizers in cold or temperate regions and sagacious administrators of tropical colonies, have failed when they attempted themselves to colonize in hot countries; why blond types prevail in the cloudy, almost sunless regions of the north of Europe, brunette types in the dazzingly light countries bordering on the Mediterranean, and the negro in Central Africa; and why the type of man living in the tireless city is less blond that that of the countryman who has during a large portion of his outdoor life the protection of woodland and orchard.

Dr. Woodruff soon convinced himself of the truth of von Schmaedel's theory, and this book contains the results of his investigations and the deductions made therefrom. It is disappointing to those of us who love the sun and the light to learn that he is not the beneficient deity we thought him to be as we worshipped, but that he delights in sacrifices and slays ruthlessly those who trust in him. It is hard to believe that man does not need the light, and it is almost a shock to be made to realize that "the vast majority of land animals live in absolute darkness." Yet the author leaves us little excuse to doubt his statements, for besides the cogency of his reasoning from universally accepted facts his pages fairly bristle with authorities whom he cites in support of his position. The only consolation is that light is a stimulant, and if taken in the moderate doses which only are possible to us in the north the good it does may outbalance the possible harm of occasional excess.

The closing chapter in this book contains practical hygienic rules for white men residing in the tropics. These are based upon the author's experience and are in harmony with the actinic theory developed in his treatise. The book is one that every white man going to the tropics can read with profit as well as interest, for it will teach him what some of the dangers are which he is to encounter, and how he may avoid them. Not the least of the benefits to medicine which have followed the North American invasion of the tropics are the many contributions, made by members of the medical corps of the army stationed in our new possessions, to the subject of tropical hygiene. One of the most practical and useful of these, as well as one of the most interesting to read is this work by Major Woodruff. The book is remarkably free from typographical errors, and we have noted but two or three in a careful reading of the volume from cover to cover. A curious misprint, however, is that on p. 177, in which Dr. Simon Flexner is accredited to the University of Paris. Doubtless he will be given his proper berth in the succeeding editions, of which we hope there will be many.

PRÉCIS DU PALUDISME. Par J. CRESPIN, Professeur Suppleant à l'Ecole de Médecine d'Alger, Médecin de l'Hôpital de Mustapha, Lauréate de l'Institut (Académie des Sciences). Paris: A. Maloine, 1904.

THIS is a useful little work, comprising within small compass a very complete summary of the latest researches into the nature and origin of malaria and the treatment of its various manifestations. It is a curious fact, to which the writer calls attention, that very little has been written on this subject in France, and, indeed, he claims that the present brochure is the first in the French language to treat fully of the subject since Laveran's work, published nearly seven years ago. The author is evidently familiar with malaria in all its forms and he possesses the happy faculty of being able to impart the knowledge, gained through practical experience, in an interesting manner.

L'OEUF HUMAIN ET LES PREMIERS STADES DE SON DÉVELOPPEMENT. *Eléments* d'Embryogénie, par J. POTOCKI, Professeur Agrégé à la Faculté de Médecine de Paris, Accoucheur des Hôpitaux; et A. BRANCA, Professeur Agrégé à la Faculté de Medécine de Paris. Préface de M. le Professeur PINARD. Avec 100 figures et 7 planches. Paris: G. Steinheil, 1905.

IN this volume, which is intended as an introduction to obstetrics, there are brought together data which have not hitherto been accesible to the physician, they having been scattered in the pages of journals devoted to pure science. The intention of the authors has been to describe the development of the human egg, and not to write a textbook of embryology. They take up seriatim: The Sexual Products, The Sexual Apparatus and Life, The First Beginnings of the Embryo (as far as the development of the embryonal layers), and The Embryonal Annexa. The illustrations are excellent, including seven beautiful colored plates. Altogether, the work appears to be an excellent one for the subject to which it relates.

PRINCIPLES OF PHYSIOLOGICAL PSYCHOLOGY. By WILHELM WUNDT, Professor of Philosophy in the University of Leipzig. Translated from the Fifth German Edition (1902) by EDWARD BRADFORD TITCHENER, Sage Professor of Psychology in the Cornell University. Vol. I, with 105 figs. in text. London: Swann, Sonnenschein & Co.; New York: The Macmillan Co., 1904.

THE author traces very interestingly the growth of the science of psychology from its mental and moral philosophy swaddling clothes, and emphasizes the vast difference between its status at the time of the first edition and the present time. The great increase in data and the immense development of the science of late years has necessitated a thorough recasting of the subject matter so that the present edition represents really a new work. It is not a mere compilation, but an interpretation from the author's standpoint, an exposition of his own experiences and convictions, though use is everywhere made of the work of others. Though all possible curtailment has been made, the two volumes of the last edition have grown to three. The present volume contains the Introduction and the Bodily Substrate of the Mental Life. The name of Prof. Titchener, who was formerly a pupil of Wundt, is a sufficient guarantee of the accuracy of the translation, concerning the difficulties of which he speaks in his preface. This volume has an index of its own.

TEN LECTURES ON BIOCHEMISTRY OF MUSCLE AND NERVE. By W. D. HALLIBURTON, M.D., F.R.S., Professor of Physiology in King's College, London, and Editor of Kirkes's "Handbook of Physiology." Philadelphia: P. Blakiston's Sons & Co., 1904.

THIS book, of 160 pages, comprises lectures on the chemical aspects of muscle and nerve phenomena, delivered by the author at the University of London, and also on the Herter foundation at the New York University and Bellevue Hospital Medical College, in this city. Those who heard those lectures will welcome them in book form. Professor Halliburton displayed a rare gift of making plain difficult points, combined with a happy success in showing that many experiments in this field are much more easy of performance and less abstruse than one would naturally suppose. The chapter headings will give a good idea of the scope of the work. They treat of: The Composition, The Heat Rigor, The Pigments and Ferments, The Extractives, and The Chemical Changes Accompanying the Contraction of Muscle; The General Composition of Nerve Tissues, Their Metabolism, The Coagulation Temperatures of Their Proteids, The Chemical Pathology of Certain Nervous Diseases, and the Degeneration and Regeneration of Nerves. A bibliography of the subject is prefixed, and the work is well indexed, and it is illustrated where necessary.

L'ANESTHÉSIE LOCALE POUR L'EXTRACTION DES DENTS. Par le Docteur E. SAUVEZ, Dentiste des Hôpitaux, Professeur à l'Ecole dentaire de Paris. Paris: Vigot Frères, 1905.

THE author of this book expresses surprise that the dental operators of England and America continue to cling to nitrous oxide as anesthetic for extractions, and the little volume is devoted to an exposition of the view that the injection of cocaine, combined in some cases with local refrigeration, forms the most satisfactory method of painless operating. Used in one per cent. solution, according to the recommendation of Reclus, there is no danger of intoxication with the alkaloid, but it appears that stovain is only half as toxic as cocaine and seems just as efficient, so that it promises better as a substitute for the natural alkaloid than the various other bodies that have been recommended for the purpose.

PRÉCIS DE CHIMIE PHYSIOLOGIQUE. Par ALLYRE CHASSEVANT, professeur agrégé à la Faculté de médecine de Paris. Paris: Félix Alcan, 1905.

THIS is a volume of 424 pages, in which the essentials of physiological chemistry are briefly outlined. It has been the author's aim to make the volume a practical reference book for physicians, and he has succeeded admirably, although for English or German readers the work has no advantages over books on the subject in these languages.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

104th Regular Meeting, Held March [illegible], 1905.

THE PRESIDENT, DR. CHARLES STEDMAN BULL, IN THE CHAIR.

Extensive Fatty Necrosis with Apparently Remittent Characters, with Involvement of the Pancreas; an Illustrative Case, Mistaken for Cholecystitis.—Dr. JOSEPH D. BRYANT reported the case of a widow, 52 years old, well nourished, with a decided general adipose development, especially of the abdominal region, and in all respects, excepting that of her special infliction, in an apparently good physical state. She had never been injured, nor had she ever before suffered aught of a severe nature excepting that which she denominated her "present illness." From attacks of this illness she had been afflicted with more or less severity at irregular intervals for three or four years. Of these attacks, three had been quite severe, especially the last one, from which she had suffered for a week. When the patient was admitted to the hospital, she complained of an acute pain, of sudden onset, which was referred mainly to the right hypochondriac and upper part of the right lumbar regions. Frequently, also, it was referred to the epigastrium, and sometimes to both at once. The pain had been present for three or four days. With the severe attack there was constant abdominal tenderness, and well-marked tension, especially in the right hypochondriac region, and later, but in a lesser degree, in the epigastrium. The tenderness was most severe and persistent below the free border of the ribs, in the neighborhood of the gall-bladder, gall ducts and the pyloric end of the stomach. Some of her previous attacks had been trivial, to which no especial attention was given, and for the relief of which only domestic remedies were employed. In all instances, the pain came on suddenly, without premonition, and in the last attack, vomiting and diarrhea were added to the list of previous symptoms. The stools were of an alternating brown or yellow color, occurring from twice to four times per diem for the first few days; afterwards less frequently.

Besides the tenderness and rigidity over the right side of the abdomen, which was most marked at a point a little below and to the left of the tip of the ninth costal cartilage, a round, movable mass was felt in this region. It was about the size of a small orange, tender to the touch and dull on percussion. Underneath it was another mass, broader, less tender, extending to the right, and movable independently of the lesser one above. The latter could be moved from side to side without disturbing the deeper one, and also was markedly depressed by a full inspiration, while the movement of the deeper body was much less noticeable. The patient complained of a dragging sensation referable to the smaller tumor on turning from side to side. When she was placed in the knee and elbow position the superficial growth pressed forward against the abdominal wall, while the deeper one appeared to be but little disturbed. The anterior tumor could be traced upward with the finger and by percussion beneath the free border of the ribs in the line of the ninth costal cartilage.

The superficial tumor was regarded as being a distended, tender, and inflamed gall-bladder by all who examined the case. It was thought that pus was present in the gall-bladder or elsewhere, because of the pronounced iodophilia test that was applied repeatedly by Mr. Goldhorn, of the Carnegie Laboratory. The deeper tumor was regarded as being inflammatory in origin, and connected with the fatty capsule of the kidney, but as to the exact nature of this especial feature of the case no one felt inclined to express a positive diagnosis. The tenderness and distention of the gall-bladder were believed to be due to cholecystitis, the result of an infection dependent no doubt on the presence of gall-stones in the sac, where they had been for an indefinite length of time, and had possibly frequently contributed to the periodical sufferings of the patient. Perhaps, now and then a gall-stone had escaped by way of the common duct into the intestine.

Before entering the hospital, the patient had suffered severely from nausea and vomiting, and as the stomach entirely refused the presence of nutriment, supporting enemata were given at proper intervals, until at last small portions of koumys and matzoon were borne by the mouth. On admission, her temperature was 102° F.; pulse, 96; respiration, 24. There was no jaundice present at this time, nor was there a history of jaundice previous to this time. A blood count showed 16,000 white cells. The urine was acid; clear; sp. gr., 1,020; it contained a trace of albumin and a few hyaline casts; no sugar nor bile. When the patient's condition had sufficiently improved, an exploratory incision was advised, but on the day set for the operation she developed a thrombosis of the left femoral vein, with all of its characteristic signs and symptoms. After these had subsided, the abdomen was opened in the median line. The gall-bladder was found to be normal in all respects as to size, location, appearance, and contents, so far as could be made out. The omentum was extensively indurated, and contracted into hard, irregular masses of varying size, the uppermost mass being the tumor that had been mistaken for the gall-bladder, while the lower proved to be the deeper tumor connected with the fatty capsule of the kidney. The connection between these two masses was composed of smaller tumors. These growths were all freely movable. Some portions of the indurations were highly vascularized, bleeding readily, and were adherent to the visceral and parietal peritoneum. This indurated mass extended across along the course of the pancreas, with which it appeared to be closely connected. Running along the surface of the mesentery and omentum were orderly rows of lentil-shaped bodies, closely associated, and feeling like strings of small beads covered with a thin, smooth membrane. Inspection of some of these bodies presenting in the line of incision disclosed lentil-shaped, yellowish colored, separate growths, of firm consistency and linear arrangement, covered with a thin membrane, suggestive of a tuberculous or malignant deposit in regular order in the lymphatic vessels. Numerous small glands were felt in the peritoneal and retroperitoneal regions. The hepatic and gall ducts were so imprisoned in the deforming adhesive masses as to prevent examination without undue delay and great danger of hemorrhage. The appearance of the lesions suggested tuberculosis or malignant disease as the probable cause of the induration, neither of which, however, would explain the long history of the patient's repeated attacks, and they were, therefore, regarded as secondary complications of something which at the time was not determinable. Many of the local changes observed were old, and apparently in a retrogressive stage, while others were recent, highly vascularized, and of active growth. A small portion was removed from between two ligatures, to prevent bleeding, and preserved for subsequent examination. The abdomen was closed without drainage, and the wound healed rapidly, leaving the patient in a fairly comfortable condition. On the fifth day after the operation, however, apparently without premonition, the patient suddenly experienced a deep sense of suffocation and promptly died from what was then regarded as a probable pulmonary embolism.

That fatty necrosis, dependent on some potent cause referable to the pancreas, was present in this case, Dr. Bryant said, was self-evident. Exactly how the fat-splitting agent of the pancreas gained access to the contiguous fat, and apparently exercised a transforming influence on similar areas at a considerable distance from the pancreas, was a matter of great importance. It had been abundantly demonstrated that injury of the pancreas, infection of its ducts, or occlusion of the same, had been followed directly and indirectly by the fat-splitting process. The appearance of the process at a distance from the organ, and the orderly arrangement of the manifestation, which had been noted in this and in other cases, seemed to warrant the belief that the

pathological agent was transmitted, in some instances, at least, by way of the lymphatics, as simple diffusion would hardly result in such orderly and well-graded lesions.

The fragment of tissue removed in the case reported above was submitted to Dr. Harlow Brooks for microscopical examination, and Dr. Bryant said that the result of his investigation, together with the autopsy findings, would be presented by Dr. Brooks.

Dr. Harlow Brooks gave a detailed report of the autopsy findings in the case reported by Dr. Bryant. He stated that the omentum was retracted into a short, thick roll, and its entire mass was studded with yellowish bodies varying from one millimetre to one centimetre in diameter. Some of these were very hard, but not calcified, and were generally spherical or oval in contour. They were united by a greatly thickened stroma, evidently of inflammatory origin. The mesentery was similarly thickened and invaded, but in every instance the endothelial covering of both mesentery and omentum appeared to be intact, as was also that of the general peritoneum. The entire retroperitoneal fat, as well as that about the kidneys and pancreas, and even the pelvic fat was literally filled with these yellow bodies, bound together by dense strands of highly vascular connective tissue. The retroperitoneal tissues were so extensively involved as to present, with the hyperplasia of the connective tissue, a complete tumor-mass of considerable size located about the pancreas and the celiac axis. The gall-bladder contained about 15 c.c. of thick, mucoid golden bile, in which were suspended numerous small, black calculi. The wall of the sac was greatly thickened, apparently as the result of the presence of a large calculus, measuring 2 x 1.5 cm., oval in form, and so situated as at times evidently to obstruct the flow of bile into the duct, though at times probably permitting its free passage, acting in the nature of a ball valve. The presence of this stone was not suspected until the bladder had been incised, owing to the smooth but thickened walls. The common duct, as well as the cystic and pancreatic ducts near their juncture, were open and normal in appearance, and the papilla of Vater in the duodenum presented no apparent lesion, it being easy to force bile from the bladder through the ducts into the gut.

The pancreas was large. Though the fat surrounding and infiltrating it was extensively involved by the masses described, these appeared to take no part in replacement of the pancreatic tissue proper. The organ showed a general connective tissue hyperplasia, and the pancreatic artery was enlarged, its walls showing marked fatty degeneration. The pancreatic duct presented no gross changes. Though the fat surrounding the kidneys and adrenal glands was extensively invaded by the nodules, neither organ seemed to be itself involved.

The immediate cause of death was undoubtedly pulmonary thrombosis, and this lesion was clearly secondary to the iliac thrombosis. Microscopical examination demonstrated the yellow nodes to be typical fat necrosis. Associated with this was very marked hyperplasia of the connective tissue stroma of the peritoneum, with occasional areas of marked cellular infiltration, plasma cells being very abundant in places, while necrotic areas immediately impinging on the peritoneum were covered by a mass of proliferating endothelial cells, strongly suggesting an endotheliomatous growth, but clearly of inflammatory origin. Microscopically, the extent of the necrosis was found to be much greater than indicated macroscopically. The pancreas showed very extensive necrosis, affecting practically all the fat contained in its interstitium, and in addition, extensive degeneration of the parenchyma cells was apparent in many places, the endothelium breaking down into a diffuse mass of granular detritus. The walls of the pancreatic duct showed extensive degeneration in many places, and the larger channels contained numerous calculi. Areas of hemorrhagic extravasation were found to be very frequent both in the pancreas and also diffusely throughout the fat elsewhere. The hypertrophic lymph nodes showed a simple, acute hyperplastic lymphadenitis, with marked anthracosis.

Dr. Francis P. Kinnicutt said another possible explanation of the pathogenesis in the extraordinarily interesting case reported by Dr. Bryant, suggested itself to him. Opie's experiments had demonstrated that the penetration of bile into the pancreas produced hemorrhagic and gangrenous pancreatitis. Flexner had shown that a similar result followed the introduction of other foreign matters. Necrosis of the parenchymatous cells and hemorrhage represented the primary action of the bile; an inflammatory action speedily followed.

A biliary or a pancreatic calculus lodged in the diverticulum of Vater too small to obstruct the orifices of the common bile duct and the pancreatic duct, but too large to pass the papilla, converted the two ducts into a continuous closed channel from which neither the bile nor the pancreatic juice could escape into the duodenum. The bile would therefore pass into the pancreas or the pancreatic juice force its way into the biliary ducts. Both the bile and the pancreatic juice were secreted at about the same (low) pressure and any difference in pressure, Opie argued, would be overcome by the muscular gall-bladder. The length of the diverticulum of Vater varied from 7 to 8 mm.; the average diameter of its duodenal orifice was 25 mm. A calculus 3 mm. in diameter, the size which obtained in Halstead's case of hemorrhagic pancreatitis, lodged in the diverticulum would therefore be too small to obstruct the orifice of the common bile-duct and the pancreatic duct, and yet too large to pass through their common opening into the duodenum. In Halstead's case the duodenal orifice was only 1 mm. in diameter.

In view of the history of long standing cholelithiasis in the present case, of the lesions of the pancreas, of evidence of the occurrence of a fat necrosis at varying intervals, Dr. Kinnicutt thought that the supposition of temporary lodgments of small biliary or possibly pancreatic calculi (numerous calculi were found in the ducts within the pancreas at autopsy) at varying intervals, in the diverticulum of Vater, offered a reasonable pathogenetic explanation in the case related.

A number of cases had been reported in which there was pathological evidence of the *recent* lodgment of calculi in the diverticulum, although no stone was found at autopsy. It should also be borne in mind that a calculus no more than 3 mm. in diameter lodged in the diverticulum might readily escape other than the closest search.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 2, 1905.

Dr. Charles L. Dana in the Chair.

UNDER THE AUSPICES OF THE SECTION ON PEDIATRICS.

Gonococcus Infection in Children.—Dr. L. Emmett Holt presented this paper. He said the subject was one that interested the genitourinary surgeon, the obstetrician, the gynecologist, and the oculist as well as the pediatrist. He gave a very complete history of his experience with the gonococcus infection in the Babies' Hospital during the past eleven years. During the first five years of this time the number of cases ranged from 10 to 15 a year. There was a larger percentage of cases of vaginitis than of any other form of this infection. There were a few cases of ophthalmia and one case of arthritis which developed in the hospital. Examinations of vaginal discharges were made in 1896 for the first time in the history of the institution. The number of cases seemed to increase, probably because more were detected. During the summers of 1899 and 1900 they had epidemics of vaginitis in their country home. Dr. Holt described the ways in which they originated and the efforts made to stamp out the disease, which was exceedingly difficult to control. At one time from three cases that were unintentionally admitted to the country home 22 secondary cases developed. Shortly after moving into their new hospital, in 1902, one case of ophthalmia was admitted, and within the next few weeks, with absolutely new, clean

wards, 11 fresh cases developed, including three of gonococcus arthritis in boys under two and one-half months old. In the year 1904 a rule was adopted that no female child should be admitted to the hospital without a microscopical examination of the vaginal secretion. The record for this year was 52 cases of vaginitis, but many of these could not have been diagnosed without the bacteriological examination. He had sought to find out to what extent vaginitis existed in other institutions, gaining his information from head nurses and hospital superintendents who came to him to ascertain how they might eradicate the disease from their institutions. The fact that children received from other hospitals and day nurseries were infected showed that the disease was prevalent elsewhere than in the institution with which he was connected. His investigations had convinced him that it was almost constantly present in children's wards. He gave detailed statistics of his investigations in order to make it evident that in the gonococcus infection one had to deal with an organism which was very widely spread and highly contagious, and one very difficult to eradicate. Dr. Holt considered the clinical manifestations of gonococcus infection in the three principal forms in which he had observed it, viz., vaginitis, ophthalmia, and arthritis. His observations were made on children under three years of age. The cases in which the infection manifested itself in other forms than those mentioned were very few. In well marked cases of vaginitis the discharge was moderately abundant, yellow or greenish yellow and occasionally tinged with blood. Extension to the uterus, tubes, and peritoneum was not observed, nor was cystitis met with; urethritis was not common and seldom severe. In mild cases the discharge might be so slight as to escape detection. Constitutional symptoms were few and insignificant. The temperature scarcely ever exceeded 101 degrees. The gonococcus was a diplococcus which decolorized when stained by Gram's method. It was necessary to find it in the pus cells in order to make a diagnosis. In vaginitis due to this infection it was usually the only bacterium present. If many leucocytes were present in the vaginal discharge of infants he regarded the cases as suspicious. A non-specific purulent vaginitis was uncommon. The use of proper local measures was difficult in young children and the disease sometimes lasted six or eight weeks. He reported 26 cases of gonococcus arthritis which he considered the most interesting phase of gonococcus infection in children. Of these cases 19 were male and 7 female. In five cases a single joint only was involved, in 16 cases three or more joints were involved. The superficial symptoms were a rapidly developing articular swelling, early redness, acute tenderness, and, in cases going on to suppuration, usually fluctuation at the end of a week. The usual characteristics were those of acute pyemic arthritis. The fever frequently reached 103° and sometimes 104° or 105°. It lasted anywhere from one to eight weeks. Wasting, prostration, and exhaustion were also usual symptoms. In many of these cases death was due to marasmus and not to pyemia. In children whose condition was fairly good incision and washing out of the affected joints usually sufficed for rapid cure. This disease closely resembled acute articular rheumatism, but as the latter was exceedingly rare in children under one year the symptoms enumerated should suggest gonococcus arthritis. He said that the most obvious means of spreading the infection was through napkins. It was customary to soak the napkins in a disinfectant, boil them in suds, and put them through a steam sterilizer. Thermometers, nipples, and bottles should be kept separate with the greatest care. Sponges and wash cloths should be interdicted in institutions and even bathtubs should be dispensed with where there was any case of this nature. The most scrupulous precautions should also be taken with reference to the nurses' hands. In cases of arthritis he suspected that the bacteria might gain entrance through the mouth. In cleansing the mouths of infants the nurse should use a toothpick wound with absorbent cotton, and not the finger. Upon the admission of children to institutions, a bacteriological examination should be required, but where this was impracticable a fold of gauze placed between the labia would be found to show even a very slight discharge. Quarantine of both child and nurse was the only means by which the spread of the disease could be checked. After an outbreak in a ward as much thoroughness in fumigation should be employed as after an outbreak of scarlet fever.

The speaker, in concluding his paper, said that (1) We must recognize gonococcus vaginitis as a very frequent disease and one to be constantly reckoned with in institutions for children. It was also very frequent in dispensary and tenement practice and not uncommon in private practice of the better sort. (2) In its milder forms and in sporadic cases it was extremely annoying because so intractible; in its severer forms it might be dangerous to life through setting up an acute gonococcus pyemia or infection of the serous membranes, and in its epidemic form it was a veritable scourge in an institution. (3) The highly contagious character of gonococcus vaginitis made it imperative that children suffering from it should not remain in wards or dormitories with other children. A similar danger though less in degree existed with the gonococcus ophthalmia and acute gonococcus arthritis or pyemia. (4) It was practically impossible to prevent the spreading of the disease if infected children remained in the wards with others. They must either be excluded from the hospital, or, if admitted, immediately quarantined. (5) Cases of gonococcus vaginitis could only be excluded from hospital wards by the systematic microscopical examination of a smear from the vaginal secretion of every child admitted. If a purulent vaginal discharge was present, such examinations were imperative and should be as much a matter of hospital routine as the taking of throat cultures in children with tonsillar exudates. In the absence of a bacteriological examination a purulent discharge in a young child might be assumed to be due to the gonococcus. (6) The quarantine to be effective must be extended to the nurses and attendants as well as the children. Napkins, bedding, and other clothing of infected children must be washed separately from that of the rest of the house. (7) When the gonococcus was found with no vaginal discharge, or with a very slight discharge, children should also be quarantined, although it was possible to say to what degree such cases might be dangerous in the ward. One of the greatest difficulties in connection with the gonococcus vaginitis arose from the prolonged quarantine rendered necessary from the fact that these cases were chronic in character and very resistant to treatment. (8) The danger to nurses from accidental infection, especially in the eyes, was very considerable. At the present time they were not sufficiently instructed in this respect.

Dr. F. C. Wood said that cultural procedures for the isolation and identification of the gonococcus were so complicated and difficult of execution that they must be left to the trained bacteriologist. The practitioner must always depend upon the morphological identification of the organism in smears. Dr. Wood said he took advantage of the sharp morphology of the organisms when stained by means of the Jenner blood stain. The smear should be spread very thin, and, when dry, should be stained in the alcoholic mixture for three minutes, when the bacteria would be fixed and stained. If the smear was taken from a case of gonococcus infection, he said it was easy to find the characteristic organisms in the bodies of the leucocytes. The Jenner stain gave a specially good differentiation because the cell body stained reddish while the gonococcus took a deep blue stain. Other cocci, such as the micrococcus catarrhalis, which had been found in the urethra, might assume the biscuit shape and also be found in the bodies of the leucocytes. It was advisable to keep some stained smears containing undoubted gonococci to control the microscopical findings. The micrococcus catarrhalis was also negative to Gram, so that this procedure offered no differential points. If after some search organisms were found which were in the pus cells,

but which did not correspond to the morphology of the gonococcus, it was convenient to do a Gram stain on top of the Jenner preparation. The slide should be ringed with some waterproof ink, or the position of the doubtful cells marked on the coordinates of the mechanical stage, and preferably after fixation of the slide by heat, a Gram stain could be carried out in the usual manner. The same group of organisms could then be re-examined and their relations to the Gram stain determined. This was somewhat more convenient than making a Gram stain first, as it was more difficult to find the organisms than with the Jenner. Special care should be taken in obtaining the material so that the difficulties of diagnosis were not increased by the presence of a large number of saprophytic bacteria which were frequently present in the vulva region. In the case of children with an abundant discharge of pus, it was advisable to pass a small platinum loop into the vagina aud urethra if possible, and thus obtain the material uncontaminated. Regarding disinfection of linen in these cases of gonococcus infection of the vagina in children, the most suitable method seemed to be the use of one of the more penetrating disinfectants, such as formaldehyde or carbolic acid, for the preliminary disinfection. All clothing should afterwards be boiled or thoroughly steamed. The gonococcus was known to be one of the most easily destroyed organisms, but sometimes a superficial disinfection with a nonpenetrating disinfectant, such as bichloride of mercury, might leave living organisms inside of a mass of mucus or pus.

Dr. J. Clifton Edgar said that from the obstetrician's standpoint, gonococcus infection in infants concerned the eyes, the mouth, the stump of the umbilical cord, and the vulvovaginal canal. These were all infections of the mucous membranes except in the case of the umbilicus, in which the infection was directly into the lymphatics or veins of the stump of the umbilical cord. Gonococcus infection of the eyes was by far the most frequent in the experience of the obstetrician. This was due to the fact that the delicate mucous membrane of the eye in the newly born offered little resistance to gonorrheal infection, and then the eyes might be injured during rough vaginal examination or during labor in face and brow presentations or in extractions of the aftercoming head in breech presentations. Our knowledge of gonococcus infections of the mouth, umbilical stump, and vagina in the newly born was very meagre, which might be due to the fact that the subject was divided among obstetricians, pediatrists, and ophthalmologists, each specialist caring only for a particular aspect of the subject. Recent writers made scarcely any distinction between gonococcus of the newborn and the same disease in young infants in general. In 1891 Rosinski first described gonorrheal stomatitis, and in 1903 Baginski first described gonococcus infection of the umbilical stump, it having been previously assumed that umbilical infection was due to ordinary pyogenic cocci. Aichel, in 1891, maintained that gonococcus infection in the vagina in the newly born had been recorded only a few times. Dr. Edgar believed that gonococcus infections, intra partum or directly post partum, of the mouth, umbilical stump, and vulva and vagina were rarely met with, because of the ligature of the cord and the nonexposed condition of the mucous membrane of the mouth and vagina. Modern prophylactic measures had reduced the frequency of gonorrheal ophthalmia from 12 per cent. to less than 2 per cent. During the past five years at the Bellevue Emergency Hospital there had been no instance of serious cord suppuration; there were four cases that had yielded readily to treatment. Several mothers who showed evidences of vaginal inflammation after labor were transferred, and in most of these cases the infants had purulent ophthalmia. No cases of sore eyes were transferred. Among 800 cases of delivery in the Out-door Tenement Service in Seventy-sixth Street, five cases of ophthalmia were recorded, and several superficial local infections of the cord. There was one death from probable gonococcus cord infection. Dr. Edgar said that the interest of the obstetrician centered in the prophylactic treatment of gonococcus infection in the newborn. The bactericidal action of the vaginal mucus did not extend to the gonococcus. According to Winckel, the fetus might be infected in utero and be born with a well-developed conjunctivitus. If the vagina was sterile usually it needed no preparation for labor, but if it was not sterile it did, and in hospital practice he believed that routine antiseptic preparation of the vagina was necessary to prevent ophthalmia neonatorum. In private practice he was not accustomed to use ante-partum vaginal irrigation; this was a concession to the belief that there was less gonococcus infection in private practice. Occasionally one met a case of gonococcus ophthalmia in spite of Credé's nitrate of silver method of prevention. Ante-partum vaginal preparation and Credé's nitrate of silver method would greatly reduce the percentage of gonorrheal ophthalmia, but they could never abolish it. The obstetrician knew of no method that would positively prevent the occurrence of gonococcus infection of the fetus when a woman was the subject of such an infection.

Dr. R. B. Kimball said the paper was particularly interesting to him because he had seen many of these cases, and shared in the vicissitudes encountered at the Babies' Hospital. The cause of the serious time there was, in all probability, the fact of the admission of babies and children with gonorrhea, although no symptoms of it were present, and the only possible way to rid the institution of the infection was in preventing the entrance of more cases. One year ago last summer, at Sea Bright, a gonococcus infection broke out; the children were isolated and the facilities for isolation were good, but in spite of every precaution the infection spread, and he believed it to have been mainly through the night nurses, who had so many changes to make during the night that it was impossible for them to keep their hands clean. One could never realize the insidious nature of the infection unless he had served in an institution for infants. It seemed strange that in the Babies' Hospital no cases were met with in the adult females, who numbered about thirty. It was also surprising that the importance of the infection was not recognized by the Health Department.

Dr. Koplik said that when he assumed charge of the Mt. Sinai Hospital service for children there was not a female child on that service who was not the subject of gonococcic infection. He said he knew of nothing more baffling than efforts to rid children of this infection, and when children were once infected he believed they were really more or less crippled for life. Because of the widespread prevalence, he was compelled to find some means to control the disease and finally he devised one of the most perfect systems of prophylaxis and isolation ever practised in this city; at the same time the system was an expensive one, 140 diapers being used in the wards daily, and the annual cost was $1,500 for this item alone. After being soiled, the diapers were burned. He visited different institutions in this city, and said he could confirm what had already been stated, that there was not an institution in the city devoted to the care of children that was not the seat of gonococcus infection, endemic and epidemic. In every instance their system of prophylaxis was imperfect. Because of his system of prophylaxis there had not been a single case of vulvovaginitis for at least two and a half years in his service. Every gonococcal case that came into his service was immediately isolated, given a separate bed, special nurses, and utensils, and the beds were marked with red ribbons to distinguish them. Every child had its own thermometer, bed pan, liquid soap, wash rag, comb which could be boiled, and wash-basin. He did not believe that diapers could be disinfected, chiefly because the nurses and other ward help could not be depended upon except for a short time to carry out the proper measures.

Dr. T. S. Southworth said that such infectious scourges as diphtheria, scarlet fever, etc., could be stamped out by well recognized measures, isolation and quarantine, but this was not the case with an outbreak of a gonococcus vaginitis,

because this disease might be latent and break out at any time. This disease among children was without doubt on the increase, and he did not believe that there was an institution in New York City that was devoted to the care of infants and children but had, at some time during the year, some cases. So soon as a single case entered the building there was danger of an epidemic unless the utmost vigilance was exercised. He considered it unsafe to admit female children from certain institutions which were known to be full of gonorrheal vaginitis. Irrigations with solutions of bichloride of mercury, nitrate of silver, or other salts of silver, were efficient when properly performed; irrigations alone, however, were not so efficacious as when they were followed by the introduction of a gauze wick, for otherwise the solution did not remain long enough in contact with the parts. He advised soaking the gauze in a five or ten per cent. solution of ichthyol, or a four to ten per cent. solution of an organic silver salt; the introduction of this prevented the walls from coming in apposition, facilitated drainage, and kept up continuous medication. The speaker emphasized the necessity of keeping on a bandage or diaper, without which the child might easily carry infection to the eyes.

Dr. Arnold Knapp said the diagnosis of a gonococcus infection of the conjunctiva in the newborn could not be made early in every case from the clinical picture; there were cases of very severe forms of conjunctivitis due to the pneumococcus or streptococcus and quite mild forms due to the gonococcus; therefore, a microscopical examination of the pus should always be made. Metastasis from the eye he did not believe occurred unless the infection traveled along the nasolacrymal canal. Many eyes had been saved through the use of the Credé method, but he considered this too severe treatment for general use. He advocated the careful cleansing of the eyelids after the birth of the child as the most important prophylactic measure. An organic salt of silver could be instilled and it acted as well as nitrate of silver as a preventative and was far less irritating. The treatment of gonococcus infection of the eyes consisted in the use of ice compresses, frequent irrigations of the conjunctival sac, and, in the later stages, silver nitrate, which he did not think could be replaced at this time by any of the recent silver preparations.

Dr. John E. Weeks said that infections of the conjunctiva were among the diseases most frequently met with by the ophthalmologist in very young children, but not so frequently among those between the ages of three and ten years. He did not believe there was an institution in New York City that was devoted to the care of young children but had had an epidemic of gonorrheal infection during some time of its existence, especially in those devoted to the care of little girls. He spoke of an interesting experience he had had in a residential school for girls, in which seven or eight cases of gonorrheal ophthalmia were discovered, and he learned of the existence of one case of vaginitis. He then requested the visiting physician to make an examination of all the girls in the institution, 87 in number, and discovered that there were as many as 22 cases of gonorrheal vaginitis. In looking over the records, he learned that, among 83,000 admissions to the Manhattan Eye and Ear Infirmary there were 400 cases of ophthalmia neonatorum. Of these 400, 60 or 70 had some palpebral lesion as well. In 80 per cent. of the cases both eyes were involved. The mode of infection was from the vaginal discharge during the birth of the child. He divided the cases into primary and secondary —primary when infection took place before or during the birth of the child, and secondary when it occurred after birth. He said cases were on record showing that infection of the eyes had occurred before rupture of the membranes. The time of onset in these cases was during the first five days after birth as a rule. When the conjunctiva was attacked late the disease was not so severe, as a rule, as when it was attacked early.

The cases that occurred later were usually due to gonococci whose virulence was attenuated and were much milder in character. The gonococcus attacked the healthy conjunctiva, might penetrate the subepithelial tissue and enter blood vessels and lymphatics. Gonorrheal arthritis was mentioned as a complication of ophthalmia neonatorum. He referred to a case in which the arthritis developed two weeks after the onset of the ophthalmia and another in which it developed three weeks after. Corneal ulcer in gonorrheal inflammation of the eye might be due to the straphylococcus or streptococcus after interference with the nutrition of the corneal epithelium by the toxin of the gonococcus. In referring to prophylaxis, he expressed the opinion that in the organic silver salts remedies were at hand which could be used after the manner of Credé, and which were fully as efficient and much less irritating than the two per cent. solution of nitrate of silver. Frequent cleansing of the eyes with a saturated solution of boric acid, and the well advised use of nitrate of silver or of an organic silver salt would seldom fail to promote recovery without impairment of vision.

Dr. Wisner R. Townsend said that in the Hospital for Ruptured and Crippled they met with but few cases in infants, the indoor patients consisting of children between the ages of four and fourteen; but in the dispensary patients of all ages were met with. Considering the topic from the orthopedist's standpoint, there were three classes of cases: (1) the periarthritic, (2) those with simple effusion into the joints, and (3) cases of mixed infection with the gonococcus present. A bacteriological examination was necessary in order to arrive at a correct diagnosis, especially in the cases where the vulvovaginitis or urethritis was not marked. In children plaster casts or braces he considered necessary, because it was an important part of the treatment to completely immobilize the affected joints. When pus was present in a joint he thought it best simply to incise but not to do a very extensive operation, even though the bone itself was infected. The prognosis in arthritis occurring in children he said was better than in adults, as asepsis was better tolerated and their recuperative powers were better. As a rule in the cases met with in the Hospital for Ruptured and Crippled with a gonorrheal vulvovaginitis very few joint complications occurred.

Dr. A. Jacobi believed that gonorrheal infections in children should be recognized by the local Board of Health, but he questioned the advisability of bringing this matter to the attention of the New York Health Department before more had been done by the members of the Academy. Two or three years should elapse first, and during this time records should be had from the various hospitals and dispensaries regarding the number of cases; then when ample material was obtained the Health Board should be asked to act officially.

Dr. Prince A. Morrow thought it would be useless to present the matter to the Department of Health, because it knew of the existence of the evil and regarded it as a *noli me tangere*.

Roof Playgrounds on City Roofs.—Dr. William P. Northrup read this paper, which was a description of the improvement that occurred in the children of a single family as the result of roof playgrounds for them. Photographs of playgrounds and children were shown.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 3, 1905.

Dr. Samuel Lloyd in the Chair.

Chronic Osteomyelitis of the Femur Treated by Iodoform Wax Filling.—Dr. C. A. Elsberg presented these patients. The first was a man 31 years of age, who entered the Mount Sinai Hospital June 14 last for chronic osteomyelitis of the lower end of the femur. In this he made use of the iodoform-wax filling, of which he said he would speak later. The patient was out of the hospital on June 30. The second case was in a boy on whom he had operated on

June 24 of this year for osteomyelitis of the femur, in which he got the same results. The patient was shown with the iodoform-wax filling still in place.

Faciohypoglossal Anastomosis.—Dr. A. S. [illegible] sented a boy upon whom he had operated three and one half months ago for a paralysis, which occurred follow[illegible] a mastoid operation. A facial anastomosis with the hypoglossal nerve above the posterior belly of the digastric was made. It was now some fifteen months since the operation was performed. Drawings were passed showing the results of operation, and also pictures to show the rapidity of its progress. After the operation there was a considerable degree of paralysis of the tongue on the right or paralyzed side. The patient was presented last year, when it was stated that in all probability the paralysis was due to the traumatism inflicted upon the nerve by the technique employed. He therefore designed certain instruments for the purpose of diminishing the degree of traumatism to the twelfth nerve, and a special knife was made for going beneath a portion of the temporal bone. The doctor presented these instruments. His last operation was done two weeks ago, by the use of these instruments, and there was practically no damage whatsoever to the twelfth nerve. He therefore felt that the operation could be done without increasing the amount of paralysis, and he also felt that, with the degree of improvement shown, one was not justified in making a transverse section of the twelfth nerve, because of the resulting permanent palsy. With this improvement that he had gotten he did not feel that he was justified at all in sacrificing the function of the twelfth nerve in order to augment the power of the seventh.

Dr. Taylor showed a similar case occurring in a lady, in whom there was some response to the electrical current, and, therefore, on whom he felt justified in peforming faciohypoglossal anastomosis, with the assistance of the instruments presented. Only two weeks had elapsed since the operation, and yet she was able to move her tongue in all directions, which showed that the twelfth nerve had not been damaged. For a few days after the operation there was a slight difficulty in talking, probably caused by the handling of the nerve. He called attention to the fact that the scar left was hardly perceptible, the greater portion of it being behind the ear and in the neck along the line of natural cleavage.

Dr. L. Pierce Clark said, regarding some of the objections that had been made to implantation of the facial on the hypoglossal, that the twelfth would be obliged to take up its own function as well as the seventh, therefore weakening the muscles supplied by the seventh as well as the twelfth would follow, because that nucleus would have to do double duty, were all theoretical objections, and not particularly borne out in practice, because of the fact that the twelfth nucleus was several times larger than any other nucleus in the medulla, and, therefore, could take up its own work as well as that of the seventh. He called attention to the fact that the seventh was a nerve of expression and not of mastication. At first he was inclined to think that the hypoglossal nerve would be damaged seriously by this operation, but Dr. Taylor's perfected technique had fully persuaded him that this nerve need not suffer any loss of function as the result of the operation.

Dr. Howard Lilienthal had always thought that it would be better to use the spinal accessory rather than the hypoglossal nerve, but now thought that he would have to change his opinion, because this nerve was so easy to get at for the purpose of anastomosis.

Dr. Elsberg referred to a patient 30 years old who had had complete palsy since childhood, with contraction of muscles, etc. A faciospinal-accessory anastomosis was performed, and the results so far had been very satisfactory, and he hoped to show the patient soon.

Dr. John F. Erdmann asked why the hypoglossal was used.

Dr. A. S. Taylor said that the hypoglossal was more easily accessible. In one of these operations by Frazier of Philadelphia the twelfth nerve was gotten [illegible] belly of the digastric. As to why he had chosen the twelfth and not the spinal accessory nerve, he did so not only because it was more accessible, but because of certain disassociation, for long periods of time, of shoulder motions. Emotional movements of the face were accompanied by disfiguring motions of the shoulder. Another good reason for choosing the twelfth was found in the fact that the centers for the seventh and twelfth were more closely associated in the cortex than the centers for the spinal accessory and the seventh. He emphasized the fact that the cortical centers needed education after transplantation.

Dr. Erdmann referred to a case in which he had performed faciospinal-accessory anastomosis. The patient now had his face movements, but they were associated with movement of the shoulder girdle muscles.

Treatment of Chronic Osteomyelitis and of Chronic Bone Cavities by the Iodoform-Paraffin Wax Filling.—Dr. Charles A. Elsberg read this paper, in which he stated that one should never leave cavities or dead spaces in bones when it could be avoided. In some tissues when cavities were left behind the walls would collapse and come in contact with each other; but in bones where the walls of the cavities were rigid, firm, and unyielding, such would not happen, and fluid material would gain access which would serve as a nidus for bacterial growth. Long bones healing by granulation required months of treatment, and the only way to succeed in getting a speedy recovery was by keeping the cavity aseptic, and changing the dressings as frequently as possible. He then referred to the various attempts made to obliterate these cavities by the introduction of substances of various kinds into them. But none gave satisfactory results except in a very few cases. The materials used often caused increased secretion or caused extrusion, and had to be removed later. Impressed by the claims made of a certain method lately exploited, he determined to give it a trial. He then described the technique of the operation, and emphasized the importance of getting the walls of the cavity perfectly dry, and thoroughly sterilized, and clearing away all dead or infected material from the hard as well as the soft tissues. Then the filling should be introduced, which consisted of a mixture of idoform 60 parts, spermaceti and sesame oil, of each 40 parts. This mixture was poured in. It required from two to three minutes for the mixture to become hard. The soft parts were then closed, except possibly with some drainage, and dressings were applied, which were not removed for from seven to fourteen days. These wounds should heal by primary union, and the patient be discharged in from two to four weeks. The iodoform-paraffin-wax filling slowly disappeared as the new tissue appeared in the cavity, and this could be well followed by *x*-ray pictures, the iodoform making the shadow. The wax mixture in some cases became extruded in a very few weeks. Iodoform poisoning was never encountered, although small amounts of iodine could be found in the urine for a few days after operation. He said this method was applicable in all forms of chronic bone disease, but not in those acute forms in which the cavities could not be rendered aseptic. This method had been employed in fifteen cases at the Mount Sinai Hospital, but the results had not been so good as those reported from abroad, although much improvement was shown over the former methods of treatment, so much so that he felt warranted in recommending it. Among the improvements that he advocated were the following: the Esmarch bandage should be removed from the limb before filling the cavity; the cavity should be flushed with peroxide of hydrogen, and then a small amount of adrenalin gauze introduced to aid in drying the cavity; he never used more than 20 per cent. iodoform in the wax; the wax should be somewhat hardened in cold water before introducing it, for he believed that by so doing he could by pressure cause it to fill more completely the little

offshoots from the cavity. While his results were still far from ideal, he thought this might be due to a lack of thoroughness in preparing the bone cavity. His results were far superior than those he had previously had, and he thought that the method should have a further trial.

Dr. Virgil P. Gibney said that he had never used the iodoform wax at all in these cases, but that he had used powdered iodoform packed in tightly as a dentist would fill a tooth. What failures he had had he thought were due to a faulty technique, either because he did not hammer it in well enough, or else because the iodoform was not sufficiently powdered.

Dr. Howard Lilienthal said that the impression given by the reader of the paper was that he was not as enthusiastic as the results of his work would warrant.

Dr. Alex V. Moschcowitz had tried this treatment outlined by Dr. Elsberg, but his results had not been so good. The operation was very tedious, and required long attempts to stop the hemorrhage and to get the cavity as dry as was necessary for ultimate success. He believed that they were using something that would not mix with blood serum, and, therefore, he employed a substance which entered into closer relationship with the blood, such as a 4 per cent. solution of agar.

Dr. Elsberg said that agar had been used for this purpose before, and that it should be remembered that in animal experimentation what held true in the cavity of the bone of a rabbit did not hold true in the bony cavity of a human being.

Treatment of Keloid by the X-Ray.—Dr. Henry Perkins Moseley said that comparatively few cases of keloid treated by the *x*-ray had appeared in literature. After describing his technique, he said that the *x*-ray afforded a valuable means of treatment of this condition, probably the most satisfactory now known. To be effective the *x*-ray must be pushed to the point of burning. So far there had been no tendency for the keloid thus treated to recur. The effects of the exposure continued for weeks after the treatment was stopped. He reported four cases.

The first case was that of a man 35 years of age who, in 1900, had a nevus of the right cheek removed. A keloid appeared, and on February 15, 1903, the patient presented a keloidal appearing mass about four inches long running downward and forward on the cheek. In all twelve treatments were given, extending from February 15 to May 19, exposures to the *x*-ray being of ten minutes' duration and employed three times a week. On May 15 an erythema began to appear, and the skin became inflamed, and the keloid became quite flattened. The patient could now shave himself with perfect freedom. The color had changed from red to white, and the sensitiveness, which had been at first very marked, had entirely disappeared.

A second case was in a young woman, a teacher in the public schools, who in 1902 had a so-called fibrous tumor removed from the anterior chest wall, which was at once followed by a keloid. During the winter and spring of 1904 she had been exposed to the *x*-ray and radium without effect. The keloid was two by two and one-half inches in extent, and raised about one-half an inch above the surface of the skin, slightly red, and not tender. Twenty-three treatments were given from July 19 to September 29. The skin was very resistant, and the treatment was pushed with fifteen-minute exposures. After September 29 no treatment was given for some weeks, and when she was next seen there was a marked diminution in the size of the keloid.

A third case occurred in a Japanese who, in October, 1901, as the result of treatment of a boil, had developed a keloid the size of a quarter of a dollar. It had been excised three times, but always returned. He was *x*-rayed from September 5, 1903, for one year, having had nineteen exposures. He had been purposely burned several times and after each period of burning he was given a long rest from treatment. The thickness had nearly disappeared, and there was still a tendency for the scar to become somewhat tender.

A fourth case was that of a man, a laborer, 28 years of age, who came to the hospital with a thickening on the anterior chest wall in 1901. In 1903 the thickening was excised, but returned larger than ever. He was given thirty-eight treatments by the *x*-ray, and was still under observation. At present the keloid was much flatter and less indurated.

Healed Keloid.—Dr. A. E. Gallant reported a somewhat unusual case. The patient was first seen November 13, 1901. His cheek had been cut by the breaking of a bottle; three weeks later the cut was opened and a small piece of glass removed. On January 21, 1902, a keloidal growth was removed. A recurrence followed, and in June, 1903, the patient reported that the operation was not successful. Without further interference the keloid disappeared spontaneously.

Dr. Arthur L. Fisk said he had been working with the *x*-ray for six or eight years, but no case of keloid had ever come to him for treatment. In looking over the literature, he found that but a very few cases had been reported, certainly not over twelve. He thought that some distinction should be made, and when we spoke of keloid and its treatment by the *x*-ray, reference should be made to the keloid scar. Many of these keloid scars would often disappear in time, but it took a long while. In some of the cases reported it did not seem that the use of the *x*-ray caused a very hasty disappearance of the keloid scars. It did relieve, though, the pain and the tenderness in the scar, in much the same way that the *x*-ray did in malignant disease.

Dr. Charles W. Allen said that a distinction should be made between the true and the pseudokeloid. The *x*-ray had a decided effect upon the true keloid, but it should be remembered that the true keloid, as well as the surgical keloid, occasionally disappeared spontaneously. He had seen true keloid go away without any treatment whatever. Although he had treated a number of scar keloids during the past three or four years, he had never had a single case of true keloid come to him for treatment. In cases of true keloid, when the *x*-ray had been used, decided benefit had been attained. In his experience with cases of pseudokeloid the *x*-ray had been used, and entirely eradicated the disease. He had employed it in keloid of the face, following a syphilitic lesion, in which there was marked facial disfigurement, with the best results. He referred to one case of keloid which followed an abscess associated with acne on the back of the neck, the abscess being the size of a small egg; this was entirely eradicated by the use of the *x*-ray. He did not believe it was so necessary to produce a marked dermatitis to cause a disappearance of the pseudokeloid.

Dr. Robert T. Morris reported the case of a young girl who had chickenpox with a scar developing just above the upper part of the sternum. Dr. Abbe had operated upon her, and a keloid occupied the site of the scar shortly afterwards. Dr. Morris operated subsequently, but the entire field of his operation became the seat of a keloid. He referred her to Dr. Morton, who made a number of *x*-ray exposures, which caused its entire disappearance. This was one of the most satisfactoy results he had ever seen. He also spoke of another case he had seen in which a keloid developed upon the back of the neck; the *x*-ray caused a rapid disappearance and an immediate cure of the trouble.

Dr. Moseley, closing the discussion, said that it was very important that these people should be burned with the *x*-ray if good results were to be expected.

The Present Status of Blood Examination in Surgical Diagnosis.—Dr. Frederic E. Sondern read this paper. (See page 452.)

Dr. Edward Quintard said that he had had several cases which bore out what Dr. Sondern had stated in his paper, especially in appendicitis, or in gangrenous cases. The

medical man should be exceedingly careful of the leucocyte count. He said that Dr. Cabot had quoted six cases of purulent peritonitis in which there was no leucocytosis whatever. If a count of the polymorphonuclears had been taken in those cases, he believed it would have been high indeed. Another series of cases in which one should be very careful was where there was a comparatively high count, 25,000, and where the leucocytosis did not go down; as a rule this meant pus. Again, in cases where the leucocytosis was progressive, without any fever or other symptoms, it probably meant the existence of pus somewhere.

Dr. Francis C. Wood said, regarding the value of the differential leucocyte count, that a case seen recently by him was strikingly in favor of Dr. Sondern's position. He reported this case.

Dr. Sondern, closing the discussion, said that in most of the textbooks and papers at present the increasing leucocytosis was often referred to. One count was not sufficient; there should be several counts, and if it was found that the count was upward, it should be concluded that pus was present, and that it was time to operate. Many counts could, of course, be made in hospital work, but not in private; seldom in private work did one have opportunity to make more than one count. Even where he had made successive observations, and there had been progressive increase in the number of leucocytes, if the percentage of polynuclears did not go up, it really meant nothing.

Chicago Surgical Society.

At the February meeting, Dr. Emil Ries reported a case of ankylosis of the jaw in a young man, 21 years of age, who was sent to him six months after he had acquired syphilis, and described the operation he performed. He also reported at length a case of extensive strictures of the rectum. Dr. S. C. Plummer reported a case of stricture of the esophagus following typhoid fever; also a case of colloid carcinoma of the cecum. Dr. Joseph F. Smith showed skiagraphs of stones in the kidney. He passed around a print, also a negative, showing several small stones congregated in the lower pole of the kidney, and two larger stones in the upper portion of the renal pelvis. The patient was operated upon, and the two larger stones were found above, and the lower mass seen in the skiagraph, which looked somewhat granular, was found to consist of eight or ten separate stones, the size of a small French pea. He showed a negative which illustrated an interesting condition. The patient had been under the care of Dr. Billings, and it was suspected that the man had a tumor in the iliac fossa. A thickening could be felt in the region of the iliac fossa on the right side; the man had a great deal of pain; he was losing weight rapidly, and it was suggested that a skiagraph be taken of this region. On examining the iliac fossa on the right side, a circular area, two and a half inches in diameter, could be seen, which was very irregular, showing that the bone was partly excavated in an irregular manner, and there was also a rather definitely outlined tumor probably of periosteal origin. The skiagraph showed the circumscribed nature of the tumor. Dr. E. C. Dudley reported a case of sarcoma which had developed from a uterine myoma, and showed a gross specimen, with some microscopical slides. It was evident from the gross appearances of the specimen that the sarcoma had developed from a uterine myoma. Before operation the sarcomatous structure filled the uterine cavity, and felt on intrauterine palpation like a retained placenta; in fact, it was so pronounced by two excellent diagnosticians. Microscopical sections, taken from various parts of the growth showed it to be a small round and small spindle-cell sarcoma, the sarcomatous cells being substantially of the same size as the red corpuscles. The interesting features of the specimens were: (1) A rather sharp demarkation between the sarcomatous cells and the myomatous cells. (2) Presence in many parts of the sarcoma of clearly defined blood-vessel walls. (3) The transition in the character of the blood-vessels from those which had walls to those which were mere blood spaces. In this case complete abdominal hysterectomy was performed on November 17, 1904. There was nothing unusual in the operation, or in the subsequent recovery of the patient.

College of Physicians of Philadelphia.

At a stated meeting held March 1, Dr. Robert N. Willson read a paper entitled "The Relief of Uremic Hemiplegia and Other Uremic States by Lowering Intracranial Pressure." He pointed out that the uremic state is due to the action of one or more toxins and probably also in some measures to intracranial pressure. He had observed a series of cases attended with coma convulsions and paralysis in which symptomatic relief at least was afforded, at times for considerable periods, by draining the cerebrospinal fluid by means of lumbar puncture. Dr. T. L. Coley read a paper entitled "The Famous Controversy Concerning the Internal Use of Cantharides—An Hisorical Sketch." Dr. Alfred C. Wood read a paper entitled "Gallstone Obstruction of the Bowel; Report of a Case; Removal of the Stone by Operation; Recovery." The patient was a woman who was seized with symptoms of intestinal obstruction, for the relief of which abdominal section was performed. A calculus weighing nearly 200 grains was found in the lower portion of the ileum and removed. Exploration disclosed the presence in the common bile-duct of a second calculus weighing 135 grains and a second incision was made and the stone removed. The pylorus was opened accidentally in the course of the operation and had to be closed by suture. Recovery was retarded by minor complications. Dr. John B. Roberts read a paper on "The Gardener's Spade Deformity and the Silver Fork Deformity in Fractures of the Carpal End of the Radius." He dwelt upon the importance in cases of fracture at the distal extremity of the radius of preserving the normal palmar concavity and of the necessity, in order to attain this end, of exerting considerable manual force in adjusting the fragments. If the distal fragment was displaced backward, as more commonly occurred from falls upon the palm, the well-known silver fork deformity resulted, whereas if the distal fragment was displaced in a palmar direction, as occurred less commonly from falls upon the dorsal aspect of the radius, the deformity that Dr. Roberts designated as gardener's spade resulted. The picture yielded to the *x*-ray was the same in both instances if taken from before backward, but the difference between the two became evident when pictures were obtained also from side to side.

Alterations in the Suprarenal Capsules in Death from Burns.—Augusto Moschini gives us the results of experiments made on rabbits to determine the changes in the suprarenal capsules after extensive burns of the skin. It has been demonstrated that these glands have the function of neutralizing or destroying poisonous products resulting from muscular work; also those of uremic poisoning, and of poisons introduced from without. The author believes that they also neutralize the poisons circulating in the blood as a result of burns. In the case of animals dying within a few hours after the burns occurred, he noted only a marked dilatation of the vessels of the suprarenal capsules; after a longer period a marked hyperemia resulted; after three to five days the capsule was increased in volume, and there was hyperplasia of the glandular epithelium, testifying to an increased activity of the organ and a proliferation of the cells. This increased activity he believes to be due to the antitoxic action of the gland toward the poisons resulting from the burns, the later producing a state of irritation in the capsules, even a necrosis, followed by a process of repair.—*Gazzetta Medica Lombarda.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 18, 1905:

	Cases.	Deaths.
Measles	383	9
Diphtheria and Croup	321	34
Scarlet Fever	219	25
Smallpox	1	1
Chickenpox	149	
Tuberculosis	505	198
Typhoid Fever	31	7
Cerebrospinal Meningitis	135	72
Typhus Fever		
Yellow Fever		
Cholera		
Totals	1,774	346

The Trypanosoma of Dourine.—Laveran considers the parasite of this disease, which is for the most part smaller than the Surra hemotozoon and considerably smaller than the organism of the rat; and in addition it presents various structural characteristics which permit of its identification. A stallion or mare usually contracts the disease during coitus. The trypanosoma or its developmental forms is present in the semen of the affected male, and is also frequently present and for long periods, but at irregular intervals in the vaginal mucus of the affected mare. The disease is transmitted by the entrance of the trypanosoma, by means of an erosion of the genital mucous membrane in either sex, but an abrasion may perhaps be unnecessary in some instances. In the stallion the preferential sites for the development of the protozoon appear to be the extremity of the penis, and later its sheath. In the mare, the vulva appears to be the usual seat in the majority of cases. Certain changes probably take place at the seat of inoculation of the "contagium," for it is unusual for the organism to enter the circulation and bring about a general infection, as evidenced by the eruption of cutaneous plaques, until a period of from 30 to 34 days have elapsed from the date of the primary infection. The author has not yet been able to determine whether the trypanosoma becomes generalized throughout the system in stallions which present for long periods the latent form of dourine, or whether the developmental form of the trypanosoma remains dormant in the swollen penile sheath of the affected animal until such time as depressing conditions reduce its vitality. Whenever a cutaneous plaque appears during the course of dourine, the trypanosoma or its developmental form will be found in it if a thorough microscopical examination of stained specimens be made. During the initial stage of plaque formation in any part of the body, the trypanosoma is present there. At a later date as long as edema persists, trypanosomata or their developmental forms are present somewhere in the edematous area. Although mature trypanosomata may not be discovered in the semen of a stallion suffering from dourine, if stained specimens be made and careful search be carried out, other forms than that of the mature protozoon will be discovered. The cerebrospinal fluid of animals which have succumbed to an acute form of the disease accompanied by nervous symptoms contains developmental forms of the organism. There are also to be found in fluid collected from the secondary swellings arising at the seat of a subcutaneous inoculation, with blood from the general circulation of a dourine-affected horse, into a susceptible animal. In the great majority of instances mares which contract dourine from a stallion during coitus will sooner or later develop the trypanosoma in the vaginal mucus, and it may be observed at intervals in the mucus during the remaining course of the disease. Mares subcutaneously inoculated with virulent dourine blood, in parts of the body other than the external genital organs, may exhibit cutaneous plaques and later cerebrospinal symptoms, but the vaginal mucus in such cases when free from blood may remain a non-infective agent. The vaginal mucus of a mare covered by a dourine-infected stallion has been found to contain the trypanosoma of dourine some months later without the animal exhibiting any symptoms of the disease or ill health. Flies can convey the trypanocoma and produce infection in healthy animals, as is the case with the Surra trypanosoma by direct inoculation; but no evidence has been brought forward up to the present time to show that flies act as intermediary hosts. Just as cattle and camels are capable of bearing the trypanosoma of Surra or its developmental forms in their blood for periods of from one to three years, so certain breeds of horses can maintain the contagium of dourine in their systems for periods of from one to four years.—*Centralblatt für Bakteriologie.*

Lymphosarcoma of the Frontal Sinuses.—P. H. Abercombie reports the case of a woman of 75 years who presented a rounded swelling, half an inch in diameter, in the middle line at the root of the nose. She had received a blow in that region many years before. The swelling was adherent to the bone, but the overlying skin was immovable. Transillumination revealed the mass to be translucent and palpation suggested fluid under pressure. Nothing escaped on tapping. Both frontal sinuses seemed clear. The mass doubled in size within a month, and was then dissected out. It was soft and attached to the bone, and a perforation through the latter communicated with both sinuses, which were filled with a similar mass. No pus was found. The microscope showed the growth to be a lymphosarcoma. Healing of the wound was without incident.—*Medical Press.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended March 18, 1905:

THE RELATION OF THE NERVOUS SYSTEM TO VISCERAL AND TROPHIC PHENOMENA.

BY JOSEPH FRAENKEL, M.D.,

NEW YORK.

THE distinction you have conferred upon me by electing me as your president is sincerely appreciated. Let me add to the expression of my gratitude the pledge that I will summon my best energies to the service of the society. Let me also ask for your collaboration and support to make the transactions of this society representative of the high position accorded to neurology among the branches of the practice of medicine.

Neurology has a glorious past. The stupendous neurological progress made in the present generation is personal knowledge to nearly all of us. The union of refined and thorough clinical methods and painstaking anatomical and histological study, has given to neurology the highest position among the diagnostic arts. Viewed with the bias of the sentiment prevailing at present, the future appears discouraging. A pessimistic attitude has crept in; the transactions of the meetings of neurologists seem to lack the animation and enthusiasm of former days. I do not know why this is, nor do I think it profitable to inquire. It has happened because it had to—it is a phase of evolution.

I do not believe that the present augurs ill for the future. Diastolic phases in individual and collective life do not necessarily indicate retrogression and degeneration; they simply mean a diastole preceding a systole. Historic evidence may be adduced to show that such phases argue progressive regeneration, and the future of neurology is therefore not what it may seem.

It is a significant fact that at the last meeting of the Suedwestdeutsche Neurologen und Irrenaerzte, it was debated with which branch neurology should cast her future lot—with internal medicine or with psychiatry. Extreme positions are inadvisable. It would seem that neurology has severed her connection with her parent science too radically and not adjusted the results of the neighboring theoretical branches to her purpose.

There is a wealth of fundamental questions awaiting investigation. New methods have been elaborated which promise us valuable aid. Chemopathology, which seems specially adapted for the elucidation of some neurological questions, with its promise of better therapeutics, is well established. The physiology of the ductless glands is closely allied to neurological themes and deserves our particular attention. We are all thoroughly dissatisfied with our conception and interpretation of the so-called functional conditions. It is encouraging to note a decidedly rational spirit in the newer literature of the subject.

My powers are limited and the time is insufficient to dilate upon what has just been said. I would ask your attention to-night to one subject which I believe to be of fundamental importance for clinical neurology and psychiatry: The relation of the nervous system (the cerebrospinal or somatic, and the vegetative, or in the language of Langley, the autonomic) to the pathology of the vegetative functions. This is a subject which has not been lacking in votaries, but has proven refractory and unyielding. A good deal of preparatory work has been done for the better understanding of the subject. Langley states "that the number of facts which have accumulated on this subject is so vast, that it is imperative to try and coordinate them." I need only cite the names of Schiff, Henle, Koelliker, Dogiel, Sherrington, Gaskell, Langley, Déjerine, Head, Huber, Jendrassik, Pavlow, Cassirer, Onuf and Collins, Laignel-Lavastine, and others, in order to show that sufficient material has been produced for clinical utilization.

So-called visceral or vegetative phenomena accompany more or less prominently organic disease of the nervous system, and constitute the chief physiognomy of all functional states and functional symptom-complexes. Trophic, vasomotor, and secretory disturbances of the skin, changes in the trophism of joints and viscera, disturbances of the physiologic rhythm of vaso- and viscero-motor innervation, perversions of visceral sensation, are often seen at the bedside, and not sufficiently appreciated. The visceral and vegetative symptoms of tabes and of hysteria are good illustrations of familiar types.

Valuable contributions to the anatomy of the vegetative nervous system have been made in the last decade. The relation between the cerebrospinal and autonomic nervous systems is being more clearly defined. According to Langley, there are three divisions of the autonomic nervous system, separated from each other by parts of the central nervous system, from which no efferent vegetative fibers originate. (1) *The Cranial Autonomic System.* This supplies visceral innervation to the muscles of the iris, the ciliary muscle, and the orbital muscle; to the heart, the blood-vessels of the mucous membranes of the head; to the walls of the gut from the mouth to the descending colon; to the muscles of the trachea and lungs; to the gastric glands, the liver, and the pancreas. (2) *The Sympathetic System,* extending from the first thoracic to the second lumbar segments. This supplies innervation to the vessels, muscles, and glands of the skin; the blood-vessels of the gut between the mouth and rectum; the blood-vessels of the lungs and the abdominal viscera; the arteries of the skeletal muscle; the muscles of the spleen, urethra, and internal generative organs. (3) *The Sacral Autonomic System.* From the second to the fourth sacral segments. This supplies innervation to the arteries of the rectum, anus, and ex-

* Presidential address delivered at the meeting of the New York Neurological Society, February 7, 1905.

ternal generative organs; to the walls of the descending colon to the end of the gut; to the walls of the bladder and urethra, and to the muscle of the external generative organs.

Afferent visceral nerves are found in man only from the first thoracic to the second lumbar segments. The second, third, and fourth lumbar segments do not receive viscero-sensory fibers. They appear again in the fifth lumbar and in the subsequent four sacral segments. This is interesting information, in connection with the facts, that eruptions of herpes zoster do not occur in the distribution of the segments which do not receive afferent fibers, and that in these territories reflected visceral pain is not observed. A further suggestive anatomic finding was recently pointed out by Morrison of London. The question of the relation of the nerve supply to hypertrophied hollow muscular organs was discussed by Hunter, and gave rise to an animated controversy. Hunter believed that the nerves of the pregnant uterus do not increase in size, and that therefore they are not concerned in the process of gestation. Morrison claims that the uterine nerves are in a "tortuous, coiled up" state in the non-pregnant uterus. As far as I have looked through the literature, this finding has not been corroborated. If it should prove correct, one can readily see the physiologic and clinical suggestions it contains. What applies to the uterus applies, evidently, also to the heart and to other hollow vegetative organs, which are capable of great changes of their lumen. It is believed by many that a part of the efferent autonomic nerves have their cell centers in the small round cells in the posterior lateral portions of the anterior horns. A large number of the afferent autonomic nerves have their nutritive centers in common with the somatic sensory nerves, in the posterior ganglia. Some of them arborize around the cell clusters of Clarke's columns. A number of visceral centers in the cord have long been known; the circulatory and respiratory centers in the medulla, the vesical, rectal, and sexual centers in the sacral and lumbar portions of the cord. Newer research (anatomic and clinical) makes the existence of isolated vegetative centers in the brain very probable.

It is further noteworthy to learn that no efferent autonomic fiber runs from the central nervous system to vegetative tissue without being interrupted by a nerve cell. For the understanding of visceral reflexes, it is well to keep in mind that the territory of the vegetative innervation, connected with a given spinal neuron, is not supplied with only one, but with more vegetative ganglia.

The innervation of the ductless glands is manifestly a matter of importance. For the suprarenals it seems established that the collection of neural tissue in the medullary portion of the gland has migrated into it, and not developed from the original glandular "*Anlage*." The relation of the parathyroids, islands of Langerhans, of the pancreas, and the paraparts of other ductless glands to the mechanism of innervation of the respective glands is still questionable. The histological position of the so-called epithelial bodies and chromaffin bodies is also a matter of acute interest. A number of experimental and pathological facts suggest their kinship to neural structure. The particular histology of the blood-vessels of the brain and their innervation are morphologic questions of broad application to physiology and pathology.

The splanchnophysiologists still discuss the neural or myogene origin of rhythmic motion. Pathological evidence favors the neurogene origin. The recent work of Carrison corroborates it. He concludes his experiments by saying: "It can now be stated as a fact that in Limulus the origin of the heart beat is nervous, not muscular, and that conduction of the impulse or the coordination of the different parts of the heart takes place through the nerves, not through the muscular tissue."

I cannot review exhaustively at this moment Pavlow's epochal contributions to the physiology of the vegetative system, particularly of the digestive apparatus. The following three points of his conclusions illustrate to some extent the clinical value of his investigations: (1) The sensory, the motor, and the secretory elements of the digestive process are under extensive neural control. (2) The peripheral end organs of the digestive apparatus have specificity analogous to the specificity of the special senses. The peripheral ganglia of the digestive apparatus show marked specificity in their responses to and selection of appropriate stimuli. For instance: The secretion of saliva from the submaxillary glands is incited by a variety of stimuli; the secretion of saliva from the parotid glands only occurs when the stimulation is exerted by means of small and dry particles. (3) A series of ingeniously devised experiments suggests a better understanding of the frequently discussed and poorly understood influence of the psyche on the soma.

The conception of augmentatory and inhibitory innervation is an important question of vegetative physiology. Painstaking and ingenious investigation has apparently not succeeded in framing it adequately. Onuf suggests that the augmentatory or inhibitory result of a stimulus is, among other things, also a function of the direction of the stimulus in regard to the cell of the respective neuron. Augmentatory influences have a cellulifugal, inhibitory influences a cellulipetal course. A heuristic principle was established by Langley when he determined the chemophysiological qualities of nicotine. He proved that nicotine temporarily paralyzes peripheral vegetative ganglia. This fact is at present employed to demonstrate the presence or absence of peripheral ganglia in the course of peripheral vegetative nerves. In this example the value of the study of the interrelation between the alkaloids and the nervous system is well illustrated. Empirically, we have learned a number of interesting facts in this regard. We know that different individuals react differently to various alkaloids. Individual idiosyncrasy conveys little more to our minds than the mere name. An analogy is easily established between individual idiosyncrasies and the predisposition to bacterial invasions. The virulence of organized and unorganized poisons is admittedly very variable. The affinity between certain anatomic structures or physiologic combinations and certain alkaloids is another curious fact. The specificity of organized poisons is here easily suggested. Finally, the fact of habituation to alkaloids is to be mentioned, and its possible analogy to acquired immunity suggested. Another analogy suggests itself here: The possible kinship between the chemical nature of the alkaloids and the products of the ductless glands. We are all familiar with the results of abuse of alkaloids upon the health and life of the nervous system. We have also learned in latter years to suspect the cause of a number of neurological conditions in a perverted function of the ductless glands.

Phenomena of disordered trophic influence are not uncommonly encountered by the neurologist. We know very little about most of them. The palmar and plantar *mâl perforant* of tabes, the cutaneous ulcerations of syringomyelia, the decubital ulcers observed in the course of organic diseases of

the cord or brain, the hysterical skin eruptions, the glossy skin, scleroderma, morphea, etc., are hardly understood. Some light may be expected from recent pathologic contributions. One variety of herpes zoster is, according to Head, due to a gangliitis posterior. The old discussion about the nature and cause of the keratitis neuroparalytica also seems closed. It is the belief of the majority that ulceration of the cornea only ensues when the fifth nerve is severed from its connection with the gasserian ganglion. When the ganglion is left in connection with the peripheral stump, no keratitis results. This shows us the fallacy of the belief that the decubitus is due only to the traumatisms to a skin robbed of its sensory protection. How often do we see patients with diseased cords confined to their beds for years, without decubitus, while others develop a foudroyant decubitus in a few days. The anatomic findings in cases of cord lesions, with and without decubitus, have not been carefully correlated. The very recent studies of Koester—experimental and pathological—lead him to the following conclusions: "A lesion of any part of the peripheral, sensory neuron, leads to sensory and trophic disturbances."

Alterations of the pigmentation of the skin are rarely observed in organic disease of the nervous system. They most frequently occur in cases of Basedow's and Addison's disease. Abnormal pigmentations of the skin are commonly seen in cachexias, particularly those due to intraabdominal disease; also in pregnancy. The initial stages of some forms of arteriosclerosis, particularly of the abdominal branches of the arteries, also show wide distribution of chloasmata. Pigment anomalies are at present commonly associated with some disturbance of the adrenals. This belief was adopted under the influence of the fact that decided change of the pigmentation is a cardinal symptom of Addison's disease, and that this disease is the result of a lesion of the adrenals. A study of the literature of the question shows: (1) A number of cases with lesions of the suprarenal glands, without pigmentation. (2) A number of cases of Addisonian pigmentation of the skin, without lesion of the suprarenals. (3) Many cases of Addison's disease, with changes in the semilunar ganglia and solar plexuses, with or without simultaneous lesion of the suprarenal glands. (4) A number of cases which clinically gave symptoms of Addison's disease, without any lesions. As a possible explanation of all these contradictory findings, the recent statements of Albert Kohn should be mentioned. He first described the chromaffin bodies, and regards them as a specified type of neural tissue. These bodies are found predominantly, but not exclusively, in the medulla of the suprarenal glands. They also accompany all the bloodvessels in smaller or larger collections. Lastly, the experiments of Erb, Jr., and others who succeeded in producing arterial degeneration in animals, by injections of suprarenal extract, deserve mention.

Atrophy of the hair of the limbs in tabetics, and hypertrichiasis in cases of poliomyelitis, are frequently seen. It is interesting to observe that, in cases of disease of the anterior horns, when the lesion is limited to the anterior horn cells, as in amyotrophic lateral sclerosis, for instance, this change of the growth of the hair does not take place. The same observation holds good in regard to the vasomotor disturbances seen in cases of poliomyelitis. In this latter instance the lesion is not strictly limited to the anterior horn cells, and invades the cell clusters at the lateral posterior portion of the anterior horn.

Atrophy of muscles severed from their connection with the peripheral nerves is a common fact. Atrophy of visceral muscles under similar conditions is doubted. Older experimenters describe it. Pavlow has not observed trophic changes in the cardiac muscle after vagal section. The pathogenesis of facial hemiatrophy also awaits definite solution. There are 170 cases of this malady on record, of which six came to autopsy. The last case reported by Loebl and Wiesel, showed changes in the trigeminus, including the gasserian ganglion.

The trophic changes of the joints in tabes and in syringomyelia, and the nature of arthritis deformans are still mysteries. Concerning the trophisms of the internal organs, it is interesting to point to an observation of Neusser. He reports a case of vagus neuritis, with apparently trophic ulcerations of the stomach. Ulcerations of the gut, after section of various parts of the abdominal sympathetic, are reported by Onuf and Collins and Laignel-Lavastine. The so-called vagus pneumonia is probably not the exclusive result of traumatisms in consequence of incoördinated deglutition. Similar considerations as expressed above about the keratitis neuroparalytica and decubitus are more applicable here.

The pituitary body is generally believed to exert trophic influence upon some parts of the skeleton. A curiosity of disordered bone trophism is reported by Marie. He found in a case of acquired osteomalacia in a man, extensive neurofibromatosis of the abdominal sympathetic system. The influence of the thyroid gland upon the general trophism is well exemplified in cases of myxedema. The cases of "progressive fatal cachexia" of Grawitz are still awaiting explanation. An interesting case of infantilism has recently been reported by Byron Bramwell, and attributed to deficient pancreatic function. The chondrodystrophies are clinical curiosities. I could find no suggestions in the literature about their possible pathogenesis. The problem of the origin of the most distressing condition of muscular dystrophies is one that we should seriously keep in mind.

A large number of the vasomotor disturbances are still puzzling problems. Oppenheim records a case of a curious unilateral edema, the autopsy of which revealed a lesion of the thoracic sympathetic of the same side. I described a case of so-called hysterical edema (edema fugax), in which I found at autopsy a small abscess severing the thoracic sympathetic of the same side. The general vasomotor ataxias observed so frequently in the course of Graves' disease, and the climacteric neurosis, are, on clinical grounds, referred to perverted function of the thyroid gland or of the ovaries, respectively. Angioneurotic edema is believed by many to be explained on a basis of toxemia. The question of erythromelalgia is still *sub judice*. Sachs and Wiener's findings of disease of blood-vessels and peripheral nerves are frequently corroborated. The condition is in danger of losing its clinical identity, and is being classed with the arterial diseases of the extremities.

The coordinated rhythm of innervation of the respiratory apparatus is often embarrassed in consequence of lesions of the nervous system. Herbert Spencer studied the influence of the cortex on the respiration. It is now known that concentrated attention produces diminution of the respiratory vigor, acceleration of the heart action, and slight extensor movements of the fingers and the neck. Clinical and pathological studies made at the neurological clinic of Winkler, in Amsterdam, proved this syndrome of disturbed respiratory and circulatory automatism to be correct. Anatomic studies made the existence of a center for these functions in the

frontal lobe probable. Divergent paths lead from these centers down through the internal capsule. These findings prepare for a better understanding of the respiratory phenomena observed in hysteria. Jackson's respiratory phenomenon of hemiplegics is not fully understood. Shallow respiratory excursions, interrupted by deep sighs, are frequently observed in cases of tumor of the brain. The respiratory phenomena in apoplectic and epileptic seizures are well known. Among the symptoms of thalamic lesions, respiratory and cardiomotor disturbances are frequently mentioned. The existence of a respiratory and vasomotor center in the medulla was known to older physiologists, and their vital importance well expressed by the term *"nœud vital."*

From the clinical standpoint, it is interesting to call attention to the fact that, in attacks of Adams Stokes' syndrome, which are due to interference with the medullary function, the relation between the respiratory and circulatory rhythm is different than in attacks of hysteria, which are supposedly due to cortical disturbance. That the work of the auxiliary respiratory muscles is frequently impaired by lesions of the cord or peripheral nerves is well known. Fleischmann describes a case of laryngeal spasm, at the autopsy of which the recurrent nerve was found imbedded in a packet of glands.

For the explanation of the spasmodic disturbances of the respiratory function, nervous asthma, tachypnea, hysterical dyspnea, little definite pathologic information is at hand. The bradycardia of direct and indirect vagal lesions is frequently described. According to Oppenheim, neuritis of the vagus is indicated by acceleration, rarely by slowing of the heart beat, by cardiac dilatation, and a systolic murmur.

In a case of sarcoma of the heart with ascending vagus neuritis, Pavlow found Adams Stokes' syndrome, without trophic disturbances of the cardiac muscle. Tachycardias, bradycardias, and various cardiac ataxias observed in hysterical and neurasthenic states are still puzzling. A goodly number is undoubtedly due to toxic states. Knieboeck describes a case of hysterical angina pectoris, in which *x*-ray inspection demonstrated a tetanic contraction of the cardiac muscle. The pathological relation between true and pseudo-angina pectoris is undecided. A case is described from Skoda's clinic, which presented in life attacks of stenocardia, with long intermissions of the heart beat. The autopsy, made by Rokitansky, revealed the cardiac plexuses and the left vagus thickened and swollen. A case of Lancereaux is on record which presented clinically attacks of angina, without symptoms referable to disease of the heart, muscle, or valves. The autopsy of this case showed the cardiac plexuses considerably thickened and infiltrated.

The vast variety of symptoms referable to disordered innervation of motion, sensation and secretion of the gastrointestinal tract, are well known to us, and often very perplexing. Only lately Oppenheim directed our attention to these phenomena in describing the costoabdominal symptom-complex. He pointed out the occurrence of marked gastrointestinal symptoms associated with disease of the middle thoracic cord. We often see cases of cord lesions which begin with visceral, particularly gastrointestinal symptoms, and which frequently are for a long time treated under this mistaken diagnosis.

In a large number of cases of lead colic, the celiac nerves and ganglia were found evidently diseased. Laignel-Lavastine describes the following very interesting case: A patient, 64 years old, had his left thigh amputated at the age of 11. Six months before death he had repeated vomiting, which failed to yield to any treatment. Later, obstinate bloody diarrhea and tympanites appeared. The autopsy showed congestion of the abdominal viscera. The dorsolumbar cord of the right side, from the tenth dorsal to the second lumber segments, was the seat of a fusiform glioma. This was situated in the posterolateral region of the gray matter, involving the anterior horns, the columns of Clarke, and the zone of entry of the posterior roots.

Experimenting on the solar plexus, Laignel-Lavastine describes four different states: (1) The sub-acute solar paralysis produced by ablation of the solar plexus in dogs, which survive operation a short time. This leads to fall of arterial pressure, vomiting, bloody diarrhea, anuria, and collapse. (2) Per-acute solar paralysis produced by ablation of the solar plexus in dogs, which do not survive the operation. Post-mortem examination shows a hyperemia of the abdominal viscera, diminution in the quantity of urine, which is of higher specific gravity, with marked indicanuria, and the presence of leucin and tyrosin in the urine. The gastric mucosa enormously hyperemic. In the duodenum and small gut, ulcerations and hemorrhages are found. The liver and spleen are enormously congested. (3) Chronic solar paralysis produced by ablation of the solar plexus in dogs, from which the animals survive a longer time. Fetid diarrhea, small pulse, oliguria, urobilinuria, and indicanuria are present. In other cases no symptoms are observed. (4) Irritation of the solar plexus. There is observed severe epigastric pain, constipation, rise of arterial pressure, cessation of heart beat.

Clinically, Laignel-Lavastine correlates this division with the following states: (1) Acute solar paralysis; hysterical peritonitis. (2) Acute solar irritation; lead colic. (3) Chronic solar syndrome; alternating paralysis and irritation, lead colic and mucomembranous colitis.

Changes in the constitution of the urine are frequently observed in nervous diseases. Albuminuria is often a symptom of pontine lesion. Glycosuria is frequently associated with disease of the posterior fossa. The symptomatology of disordered genital functions is also at present beginning to be studied along the lines suggested in this paper. It is significant to read in Lubarsch and Ostertag the following: "Atrophic chronic parametritis alone, or in connection with other lesions of the female genital organs, is, up to the present time (1896), the only definitely proven basis of hysteria in women. Ascending neuritis and perineuritis mediate the production of the symptoms."

In closing I will ask your pardon for the fragmentary and cursory nature of these remarks. I have chosen the subject in spite of its vastness, and my inability to do justice to it, as an antidote to the pessimistic spirit about the future of neurology which pervades our ranks and is entertained by our neighbors.

Thorough study of the subjects outlined promises us: (1) Greater exactness of localization of organic disease of the nervous system and better interpretation of early symptoms. (2) More rational conception of functional conditions. (3) Clearer therapeutic indications.

It may be objected that this means an illegitimate extension of the neurologist's field. I do not believe so.

"A small circle narrows his mind; man grows with his larger aims."

PERINEUM, PERINEORRHAPHY, AND PROLAPSE.*

By ARNOLD STURMDORF, M.D.,
NEW YORK.
GYNECOLOGIST TO THE SYDENHAM HOSPITAL, ETC.

Sanctioned by common usage and serving for brevity, the terms perineum and perineorrhaphy are utilized to-day in a generic sense embracing all the integral structures of the pelvic floor that physiologically and mechanically combine for the support of the pelvic contents.

Among the accidents of parturition, none dominates to a greater degree the remote welfare of the patient and reputation of the attendant, than laceration or impairment of these supporting structures; no maternal injury incidental to labor demands more prompt and accurate topographical restoration, and no restorative procedure exacts more intimate regional knowledge and greater technical skill.

Although this accident and its consequences had attracted the study of the most ancient writers, no curative attempt finds record until Ambroise Paré proposed sutural readjustment of the injured tissues. From this period to the present, the stages in the evolution of perineorrhaphy are linked with the names of the most illustrious exponents of the surgical art, and while thus presenting one of the most classic and prolific of gynecologic themes, it is at the same time the most incomplete chapter in gynecologic literature:—a voluminous chronicle of surgical ingenuity and a most barren exposition of essential fundamentals.

"To no department of gynecology," said Thomas, twenty-five years ago, "does there attach more surgical rubbish which needs a thorough clearing away;" and in a large measure this assertion holds good at the present time.

Perineorrhaphy has afforded a most fruitful field for attempts at originality and innovation: regardless of the principle that "progress is characterized by simplicity," countless diverse and complex methods have been introduced by successive investigators who, losing sight of fundamental principles, seemed only to strive for some peculiarity of procedure which they could call their own. The result is, that many of these procedures defeat the object of operation, by substituting for normal physiologic support, a pathologic obstruction, represented by a cicatricial mass, uniting dissimilar tissues and serving as a mere retention plug at the vaginal outlet.

Obstructive retention cannot replace normal visceral support, and the immediate aim in perineorrhaphy should be based on the elementary surgical principle of accurate restitution of original anatomic relations thus restoring, as far as possible, *functional* as well as mechanical support to the pelvic contents.

The keynote in the clinical significance and therapeutic indication of pelvic floor laceration is *prolapse*: while perineorrhaphy, immediate, intermediate, and late, represent respectively the prophylaxis and cure of such prolapse. Visceral prolapse is pathologic visceral support, and its restitution must be based upon a clear conception of the mechanism of normal support.

It is not the purpose of this communication to present an elementary review of those anatomical and physiological data, which represent the modern accepted factors concerned in the normal support of the pelvic contents; this is common and accessible knowledge, but to submit for consideration certain factors, whose dominating influence on pelvic visceral equilibrium has not, to the present writing found record.

Our knowledge of the nature of pelvic visceral support has been considerably amplified within the last three decades, but has not reached finality or precision. The ancient cutaneous perineum is obsolete; the so-called perineal body has dwindled in dignity as its purely complemental function became manifest, and at the present time the *muscular* and *fascial* equipment of the pelvic floor and viscera, sways the gynecological mind in the questions of genital support. That the functional integrity of such muscular and fascial elements is all essential to normal visceral support, is established beyond controversy, but that such elements, while essential, are not indispensable to support, is exemplified by the frequent existence of extensive destruction of these tissues without the occurrence of prolapse and by the equally numerous instances of prolapse without impairment of the muscular or fascial integrity of the pelvic floor. And more significant the observation, that many technically perfect perineorrhaphies, utterly fail to restore and often aggravate the distortion of visceral equilibrium.

Studies of pelvic visceral support have been confined largely to the limits of structural detail: anatomy as such, however, has not fully explained the *mechanism* of support. It is a gross misconception of function, to attribute visceral support to textural strength of ligament or muscle; the muscle or ligament is not created that can permanently withstand, by its structural resistance, the continuous force of intraabdominal pressure. These muscular and ligamentous elements serve to support the pelvic contents, *not* by virtue of their textural resistance to displacement, but by *deflecting* the displacing force of intraabdominal pressure: and paradoxical as it may seem, both the maintenance and disturbance of pelvic visceral equilibrium, are the resultants of one and the same force, namely—intraabdominal pressure under the influence of balanced or unbalanced deflection. The influence of pressure and deflection on fetal expulsion is a familiar phenomenon, while the same influence dominating visceral displacements is unrecognized.

Briefly stated, intraabdominal pressure is the resultant of several components, the most potent of which are muscular contraction, gravity, intravisceral and atmospheric pressure. Intraabdominal pressure, while constant, varies in intensity, being augmented or diminished by the varying activity of its muscular component: its direction is influenced by certain planes, some of which are fixed and permanent, while others are mobile. In the pelvis, the fixed planes may for convenience of illustration be designated as the expulsive planes, inasmuch as they tend to deflect the direction of pressure, into line with the axis of the pelvic outlet: any viscus brought under the influence of these expulsive planes must eventually prolapse. In the same sense, the mobile planes are retentive planes, in so far as they deflect pressure in a direction to preserve visceral equilibrium. An intrapelvic and an extrapelvic deflecting mechanism, exercising harmonious and reciprocally balancing influences, maintain the topographic stability of the pelvic contents. The intrapelvic mechanism is represented by the uterus with its ligamentous extensions: the extrapelvic deflector comprising the muscular and fascial elements of the pelvic floor.

Under ordinary conditions, the direction of intraabdominal pressure within the pelvis is such as to fall upon the posterior surface of the uterus and broad ligaments: in deflecting the direction of this pressure to preserve its equilibrium, the normally anteverted uterus may be compared to a lever of

* Read before the Medical Association of the Greater City of New York, February 15, 1905.

unequal arms, poised over a fulcrum formed by the intravaginal perineal crest; the longer anterior arm of the uterine lever resting upon subjacent structures, is movable upwards, extreme movement in this direction being limited by the round ligaments, which tend to prevent tilting of the uterus into the axes of the expulsive planes: the shorter posterior arm of the uterine lever is free, being represented by the cervix projecting into the cul de sac of the posterior vaginal fornix. By this adjustment, intra-abdominal pressure will at first tend to lower the level of the uterine plane as a whole, until its anterior pole is arrested by the resistance of the subjacent bladder and posterior pubic surface; the pressure augmented, the posterior free pole, represented by the cervix, continues to descend, and forcing the lever upon its fulcrum tilts the anterior arm upward.

Were the pressure to continue without deflection, this upward tilt of the anterior arm must continue and, extending beyond the perpendicular, would retrovert the uterus and force its long axis into line with that of the vaginal outlet: in other words, anteversion would be converted into retroversion, which exposes the anterior instead of the posterior uterine surface to the force of intraabdominal pressure; this misdirected pressure will gradually lower the plane of the retroverted uterus, until its axis coincides with those of the expulsive planes, and prolapse must ensue: but, under otherwise normal conditions, deflection takes place, and prolapse is averted by the integrity of the perineal musculature.

The stimulus that excites the muscular component of intraabdominal pressure into activity, induces a simultaneous contraction in the perineal musculature. The elements of this musculature are so arranged, that their contraction elevates the perineal plane; this elevation carries the perineal fulcrum to the uterine lever, raises the depressed posterior arm of this lever to the level of its anterior arm, thus restoring anteversion; at the same time, this elevation of the perineal plane narrows the essential utero-vaginal angle, preserves the potentiality of the vagina by converting its actual canal into a valvular slit and practically closes the pelvic cavity.

Such are the functions of the perineum and such the measure of its importance as a visceral support; it follows that the gravity of perineal lacerations is proportionate to the resulting impairment of its muscular function; such impairment induces a tendency to prolapse, *not* because any direct support of the viscera is severed, but because the equilibrium of intrapelvic pressure is disturbed and its expulsive force undeflected. A study of the perineum before and immediately after puerperal injury shows that laceration *as such* does not destroy, but simply severs, the involved tissues, and the aim in perineorrhapy should be, the reunion of such severed elements and not simply the reconstruction of perineal bulk and contours. A union of muscle to fascia will restore such bulk, but does not restore *function,* and it cannot be sufficiently emphasized, that the accurate readjustment of the original anatomic elements essential for the full restoration of function, is attainable to the fullest degree *only* in the *immediate* operation.

In the immediate operation such a union is only a question of retention in accurate coaptation; postpone this simple procedure and the severed muscle fibers will retract; thrown out of function they will degenerate; cicatricial tissue will replace and displace them with resulting topographic and visceral distortions. The longer the interval between the injury and restoration, the more numerous and difficult of solution become the complicating problems, and, at the very best, the results of late operation only represent a more or less efficient substitute for immediate repair, while at the very worst, the condition may eventuate in the necessity for extirpation and obliteration of the entire generative tract. We can reunite a severed tissue, but can never restore a lost or degenerated one, and in this sense, the immediate and late operations really stand in the relation to one another of prophylaxis and cure.

In the immediate operation the obliteration of structural features by the traumatic tumefaction complicating perineal injuries, will at times present an embarrassing problem in accurate coaptation, especially to the occasional operator. Yet, to plunge a suture blindly around a perineal laceration is a procedure to be emphatically condemned as obsolete, unsurgical, and often directly injurious: proper readjustment of the injured parts demands *suture on the lines* and to the extent of the laceration both *within* and *without* the parturient canal.

To facilitate accurate readjustment of original anatomic relations, the preliminary introduction of what may be termed guide sutures, will be found helpful, time-saving, and, to some extent, prophylactic. At some convenient moment, prior to the descent of the fetal presenting part, two to three silkworm sutures are introduced under proper precautions into the structures between vagina and rectum, from the cutaneous base of the perineum to its apex; the lowest suture running on a line with the anterior anal margin, will serve to locate the several sphincteral ends; the median suture embraces the levator fibers, while the upper one will tend to coaptate the vaginal lesion. These ligatures are tied loose enough to prevent undue tension or obstruction during fetal expulsion, and at the termination of labor may be discarded if found unnecessary; on the other hand, one or more may be retained, according to indications and tied permanently, while in extensive injury they will serve as guides and retentive bands, facilitating permanent coaptation. It would hardly seem necessary to state, that in passing these preliminary sutures, neither the vaginal nor the rectal walls should be punctured.

The object of the present communication is to elucidate the principles and not the methods of perineorrhaphy: the location, extent, direction, and effect of perineal lacerations show no uniformity, and it follows that no stereotyped method can possibly find uniform adaptability, notwithstanding the recognized authority of the name linked to such method.

But while there can be no typical method of perineorrhaphy, there should be some method *in* perineorrhapy, and such method must be based upon a clear conception of the functional relations of the perineum as a link in the supporting mechanism of the pelvic contents. As previously stated, extensive perineal laceration may exist without inducing prolapse; a condition in which the other links in the mechanism assume a compensatory readjustment, productive of vicarious support: on the other hand, structural, topographic or mechanical disarrangement in any of these links, independent of perineal involvement, may be productive of prolapse.

The immediate operation being omitted, a failure, or deferred, the first essential in the late operation is the recognition of the degree in which these individual links of the supporting mechanisms are involved.

The measure of pelvic visceral equilibrium is the topographic stability of the uterus under conditions of augmented pressure, induced by the patient's expulsive efforts in the erect or squatting posture. A uterus presenting normal relations in dorsal examination, will often assume a pathologic position in the erect posture; such pathologic position may

represent its incipient prolapse, and if uncorrected, the most elaborate perineorrhaphy will fail to check its downward progress. Every pathologic condition of the uterus should be corrected, to restore its function as a deflecting lever, before perineal repair is attempted; the involutional disturbances induced by lacerations of the cervix demanding special consideration.

Immediate trachelorrhapy would correct this most frequent cause of subinvolution, and is worthy of more general adoption. Unfortunately this immediate repair of a cervical laceration is a procedure almost unknown, although simpler, more certain of result, and oftener and in many ways more beneficial than the late operation, which, while closing the cervical rent, cannot always remove the results of long-standing nutritional disturbances, and such, remaining uninfluenced, furnish a cause of failure in the late operations for prolapse.

Not only existing pathologic conditions, but pathologic positions of the uterus must be corrected as an essential preliminary in perineorrhaphy: in malpositions of long standing, with resulting insufficiency of the uterine ligaments, the permanency of positional restitution should be secured by intra-abdominal or intravaginal shortening of such insufficient ligaments, and under no circumstances is it proper or justifiable to immobilize either pole of the uterine lever, by any form of permanent ventrofixation or dorsofixation. The uterine lever restored to functional position and condition, the questions involved in the repair of the perineal mechanism present themselves.

From the clinical standpoint, two forms of vaginal protrusions result from perineal lacerations, which may exist singly or combined. For convenience these two forms may be described as false and true prolapse. False prolapse is the simple protrusion of redundant and relaxed vaginal wall and represents the condition usually cured by the stereotyped operations in vogue; these remove various patterns of the redundant vaginal tissues and reef some of its fascial attachments. True prolapse, on the other hand, is represented by the vaginal herniæ of bladder, rectum and uterus, and is not always cured by the above-mentioned procedures.

The surgical objective point in these latter cases must be that part of the perineal musculature usually involved in puerperal injury,—namely, the broad anterior loop of the levator ani, which, springing from the posterior surface of the pubic rami, passes downward and embraces the lateral and posterior walls of the vagina. In the normal state this loop is distinctly palpable from within the vagina and rectum, as a broad resilient band, which stretches under the vaginal wall from one pubic ramus to the other, on a plane posterior to that of the pubic arch. Under all conditions of perineal rupture, *the pubic attachments* of this levator loop, *present permanent palpable ridges.* With these ridges serving as guides to the muscle, the postero-lateral muco-cutaneous junction of the vagina is severed and the deep seat of lesion exposed by carefully raising the cicatrized vaginal coverings. Utilizable remnants of the levator muscle can thus be readily located, and after isolation and trimming, should be coaptated by buried end-to-end sutures.

Having secured muscular readjustment, the raised vaginal flap is permitted to settle into position, and then only should such of its redundant tissue be sacrificed as may not be utilized in restoring the contours and bulk of vagina and perineum. Trimming and suturing should be limited as far as possible to the cicatrices and lateral sulci, preserving the median aspects of the vaginal walls as much as possible.

The readjustment of the intravaginal conditions will vary according to the nature and extent of the original lesion and its consequences: no two cases are similar, and the essential phase of this part in the reparative attempt is the restoration of the intravaginal perineal crest, which represents the fulcrum to the uterine lever. The apex of this crest must be so situated as to correspond to the cervico-corporal junction of the uterus and the cervix must project free beyond it.

Let the operator fully understand what he sets out to accomplish and he will readily adopt the simplest, easiest, and surest method to this end; let him, on the other hand, clog his mind with details and special plans of this and that operator, and he will be led to adopt an uncertain mixture of complicated, and often futile, procedures.

There is much that should be added to the different phases of this topic, that has been consciously but necessarily omitted, for, within the allotted time, it would require a master of our language to depict with lucid brevity, the many essential details of our theme. I can present only this fragmentary effort, in the conviction that, when a thoroughly scientific and satisfactory essay on perineorrhaphy is written, it will not be a description of the numerous operations in vogue, but will treat in a general way of operating to restore the involved parts to the relations, conditions, and functions that prevailed before injury.

Fifty-one West Seventy-fourth Street

COMPOUND TRAUMATIC SEPARATION OF THE LOWER EPIPHYSIS OF THE FEMUR.*

By GILBERT GEOFFREY COTTAM, M.D.,
ROCK RAPIDS, IOWA.

The gravity of this injury may be inferred from a summary of the fifty cases collected by Mr. Poland (Traumatic Separation of the Epiphyses, London, 1898, page 793). Of these, thirty-three underwent amputation, with eighteen recoveries, eight deaths and result not stated in seven. The remaining seventeen were treated conservatively, with thirteen recoveries and four deaths.

The fact that about one-half of the number occurred in the preantiseptic period suggests the conclusion that a better showing might have been made had all been treated by modern methods. This is undoubtedly correct as to the saving of limb, but as to the saving of life, the case-records show that the mortality rate has been as heavy since 1885 as before.

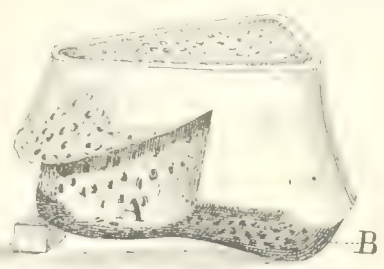

Fig. 1.—Anterior view of the piece of shaft of the femur resected, showing at A the defect caused by the disruption of the wedge-shaped fragment of bone which remained attached to the epiphysis. At B is the epiphyseal line.

The danger to life in these cases accrues from shock, gangrene and infection. The first, as would be expected in accidents of such magnitude, is generally

*Read by title before the Western Surgical and Gynecological Association at its annual meeting, held in Milwaukee on December 28 and 29, 1904.

present in some degree of severity and is credited with causing six of the deaths in Mr. Poland's series (only three of these, however, directly due to the accident, the other three following amputation). Gangrene occurs in the cases wherein the popliteal vessels are injured—which occurs in about 25 per

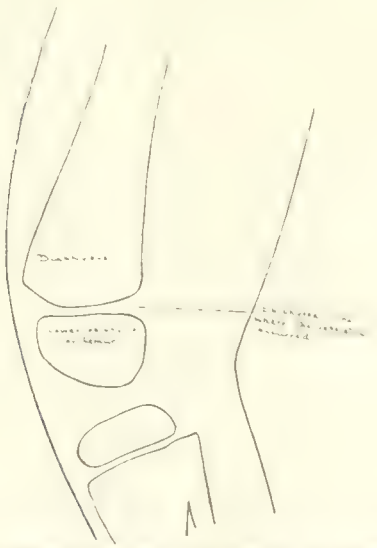

Fig. 2.—Skiagraphic tracing (lateral view) of Case I taken [illegible] after the receipt of the injury.

cent. of the cases—unless obviated by early amputation. Infection, as in all other open, accidental wounds, must be reckoned with, and upon the surgeon's ability to control it depends everything.

The object of this paper is not to make an exhaustive analysis of the subject. This has been done elsewhere, and those who wish to look into it further will find an adequate consideration of the matter in Mr. Poland's work, while for a compact résumé

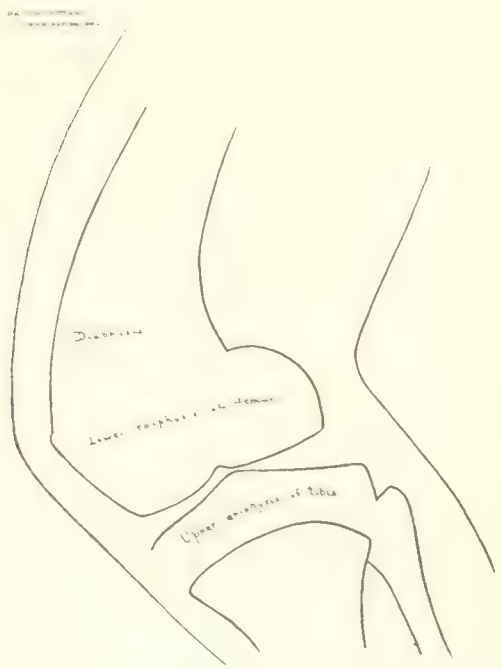

Fig. 3.—Skiagraphic tracing (anteroposterior view) of Case I; taken five and a half years after the receipt of the injury, showing "bowing" of the femur due to irregular development of the shaft, with resultant genu valgum.

brought down to the present date, I commend attention to the report of M. Kirmisson, of Paris, presented at the French Congress of Surgery in October, 1904, for a copy of which I am indebted to the courtesy of the author. The two cases which it has been my fortune to observe, occurred five-and-a-half years and six weeks ago, respectively. In the former case, therefore, sufficient time has elapsed to enable me to report the effect of the injury upon the growth of the femur. The early history of the case was reported fully by me to the Iowa State Association of Railway Surgeons, and published in the *Railway Surgeon*, December 26, 1899. I need, therefore, repeat only its salient features.

Case I.—Wesley G., aged six years and nine months, was riding with some other children in a buggy on July 30, 1899, and letting his left leg hang outside and the foot rattle against the spokes of the wheel. An entanglement resulted and he was dragged out of the buggy and thrown to the ground. The other children picked him up and took him home, a distance of one and a half miles, where I saw him in consultation with the family physician. An examination showed the protrusion of about five centimeters of the diaphysis of the femur through a transverse wound in the left biceps femoris and skin, at the outer margin of the popliteal space. It was denuded of periosteum and showed the characteristic nodulated end. The epiphyseal line had not been closely followed, a wedge-shaped fragment from the anterior and inner aspect of the diaphysis having

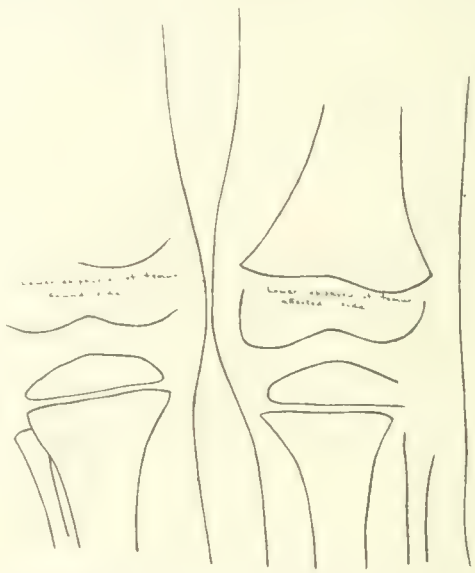

Fig. 4.—Skiagraphic tracing of both knees (anteroposterior view) of Case II; taken six weeks after the Injury.

been detached with the epiphysis. The popliteal vessels were intact and the peroneal nerve had escaped injury. The epiphysis was tilted backward. Under anesthesia I enlarged the opening by making a longitudinal incision through the center of the wound and succeeded in replacing the shaft, but so great was the contraction of the thigh muscles that the least movement caused the fragments to fly apart with great violence. I therefore resected three centimeters of the diaphysis (Figure 1), and could then effect reduction easily, although it was necessary to drill and wire in order to secure continued apposition of the fragments. The large external wound was left open and the entire extremity in full extension put up in plaster of Paris. The primary result was very satisfactory. Granulation proceeded rapidly and in six weeks the wound in the soft parts was entirely closed. The cast was discontinued at the end of the ninth week and an *x*-ray examination shortly afterward showed the fragments to be in correct apposition. At the nineteenth week the joint function was found to be fully restored and the boy could walk and run without perceptible limp, unaided by stick or crutches.

The subsequent history of this case shows the development of a curious and interesting condition. As the boy's growth proceeded, it was noticed that the knee on the injured side was becoming more and more "knocked." When my attention was first called to this, I formed the opinion, which was strengthened by careful examination, that the deformity was due to arrest of growth of the outer condyle, the inner continuing to develop. This I associated with the fact that the epiphyseal cartilage on the inner and anterior aspect was undisturbed by the injury, and the growth at that point had, therefore, been uninterfered with. But, on making a skiagraphic examination recently, I found the entire fault to be with the shaft, the inner part of which seems to be trying to develop normally, while the growth of the outer part is arrested, producing a condition of "bowing," with the concavity outward, as shown in Figure 3. The long axis of the thigh and that of the leg form an angle of 130° at the knee, externally. The circumference of the left thigh, 18 centimeters below the fold of the groin, is 41.25 centimeters; of the right at the same point 45.75 centimeters. At a point 7.5 centimeters below the left knee, the circumference measures 30.4 centimeters; at the same point on the right side, 31.6 centimeters. From the anterior superior spinous process of the ilium to the lower border of the inner condyle the measurements are: Right, 42.8 centimeters; left, the same. From the same pelvic point to the lower margin of the outer condyle the measurements are: Right, 40.4 centimeters; left, 34.2 centimeters. Thus, while the inner side of the femur on the injured extremity has kept pace with its fellow or even done a little better, since 3 centimeters were removed at the opration, the outer side shows a discrepancy of 6.2 centimeters. It is evident that the deformity could be properly remedied by an osteotomy, and if the parents of the boy can ever be brought to understand that this will not mean a repetition of the original injury, with all its dangers, it will be done.

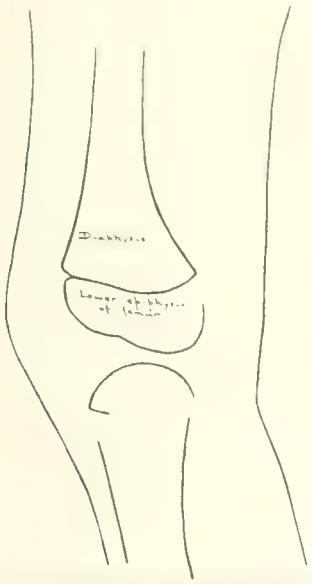

Fig. 3.—Skiagraphic tracing (lateral view) of the [illegible] taken at the same time as Fig. 4.

Case II.—Theodore S., aged five years and nine months, was trying to climb into a buggy in motion on November 9, 1904, when his left boot became entangled in the spokes of one of the wheels and he was thrown violently to the ground. I saw him the same night, in consultation with his physician, near Steen, Minn., and found a condition almost precisely similar to that described in the preceding case. The diaphysis had penetrated the biceps femoris just above the knee and protruded about 4.5 centimeters through the skin, and was stripped of its periosteum. As in the other case, the popliteal vessels and peroneal nerve were uninjured, and a piece of bone had been broken off the anterior surface of the lower end of the shaft. In this case I found this detached portion broken into several parts and removed them with a sequestrum forceps. The epiphysis was not displaced. Under chloroform, reduction was readily accomplished, and, once reduced, the fragments showed no tendency to displacement. The large opening in the soft parts was packed with gauze and the extremity placed upon a double inclined plane. At the end of the fifth week the knee was put up straight in plaster of Paris and at the present time, seven weeks after the receipt of the injury the wound in the soft parts is nearly well and union appears to be proceeding normally. Figures 4 and 5 show the skiagraphic record of the case at this time.

THE VALUE OF THE PRESENT QUANTITATIVE TESTS FOR HEARING; WITH THE DEMONSTRATION OF A NEW APPARATUS.*

By W. SOHIER BRYANT, M. D.
NEW YORK

Many methods and various contrivances have been and are still used in acoumetry. The more complicated ones have never been popular, while the simpler means, though old, are still used and are still the generally accepted standard in spite of their lack of accuracy and the difficulties of application. For the most part the complicated machines are electrical devices, and although strongly recommended, are open to nearly the same objections as the simpler means. Their special advantages are due to changes in the electric current, and their intricate construction.

The Committee of Acoumetry of the last International Congress of Otology reported on the choice of a simple and practical acoumetric formula, which advised the oldest and simplest means of testing hearing. They stated that they did so in spite of the inherent imperfections in these methods, because none better were to be had. The tests recommended by the committee were: Whispered and conversational speech, acoumeter or watch, tuning forks, and König rods.

The results of hearing tests vary considerably. One obtains different results if one brings the sounding body towards the patient from those obtained by taking it further away. As a rule the sounds are heard much further when the body recedes than when it approaches. Auditory after-impressions and psychological states explain these phenomena. The ear is not unlike the eye; a receding object is distinguishable much further than the same object when it approaches the eye from beyond the range of vision.

During the tests the eyes of the patient must be covered or directed away from the operator, whose reflected image must not be allowed to reach the patient. It is remarkable how much a slight visual hint will do in the way of increasing the hearing distance of a quick, intelligent patient.

Sentences and words are heard correctly much further than disconnected polysyllables. Polysyllables again are heard much further than disconnected

*Read before the Otological Section of the New York Academy of Medicine, and before the Otological Section of the Fourth Pan-American Medical Congress, Panama, January 2-6, 1904.

monosyllables, because in each of these cases there is less opportunity to supplement the sound by clever guessing when it is not distinctly heard.

One must bear in mind that a little sound entering the other ear increases greatly the sound perception in the ear under examination, since binaural audition is much more perfect than nonaural, and therefore the ear not under test should be hermetically closed. A slight pressure with the moistened finger in the meatus is the simplest way of accomplishing this. Too much pressure in the meatus will lower the sound perception of the other ear, and therefore must be avoided. The other precautionary measures in unilateral testing are: First try with the other ear closed, then with both ears closed; the differences thus found in the results can be credited to the ear under examination, but this gives no sound basis of comparison.

Quantitative hearing tests by air conduction should cover the whole auditory field for high and low notes alike, because the total quantitative estimate is made up of the sum of its integral parts, and no part of the scale should be omitted. Therefore, the tuning fork and König's rods tests are included among the quantitative tests.

Whispering Test.—The forced whisper, using the residual air after a natural expiration, gives a more accurate and more easily repeated test than the conversation voice, but tests obtained in this way are not the measure of the hearing for spoken words, nor can this test be repeated with perfect accuracy, because the intensity, pitch and quality are not constant. In whispered tests, the different pitch and intensity of the various vowel and consonant sounds must not be forgotten. These require that the same words must be used to make the tests comparable. A whisper allows a rough test of the auditory field by the use of letters having a wide range on the musical scale, from Re to Si, and covering the whole auditory field.

The different intensity and pitch of the letter sounds give different carrying powers. Unfortunately there is no agreement among the various authors as to the actual relative importance or the true value of these factors. Vowel sounds vary in different languages and dialects, and are influenced by the consonant preceding or following them. Consonants have a very wide range of intensity and pitch.

Conversational Test.—The difficulties in testing with the conversational voice are considerable, and it is impossible to eliminate the conditions which cause inaccuracies in the results. These are chiefly the variability in intensity, pitch, clearness of articulation, and quality, as well as the accent of the examiner. Practice diminishes the variations which the voice shows at different times, but never wholly overcomes them. They make a great difference in the carrying power of the voice, and its intelligibility, sufficient to prevent the accurate comparison of one observer's results with another's, or with his own previous tests. The different values of the vowels and consonants must be borne in mind, as in the whispered test.

In unilateral testing, it is admitted that with the spoken voice, the sound enters the other ear, no matter how it may be closed. For this reason, spoken voice tests can approximate accuracy only when both ears are tested together or when the other ear is much deafer than the one under examination. The usual method of making unilateral tests is to compare the results found with one ear closed, and those found with both ears closed. This gives no sound basis of comparison, but in practice the difference found is credited to the ear under examination.

Politzer emphasizes the value of testing bilateral hearing, because it gives the true hearing efficiency possessed by the patient for the avocations of life, and does away with the attempt to test the voice perception of one ear alone, which is, as I stated, always inaccurate.

Voice tests with words, in cases where there is a slow action of the auditory word memory, will show apparently less perfect hearing compared with mechanical sounds, just as reading is slow when the visual word memory acts slowly. Familiar sounds or known voices are heard more distinctly than new ones. The faculty some people have of reading the lips is another possible source of error which it is hard to eliminate entirely, without the greatest care. Another objection to the speaking voice tests is the considerable space required by the tests for ordinary or even low conversational voice. There is no constant relation between the hearing for whispered and that for spoken words. For these various reasons, the mechanical tests are usually employed in addition to the voice tests. Why else use the mechanical tests, except as a control for the voice tests?

Mechanical testing devices—watch, acoumeter, and tuning fork—cannot be duplicated exactly on the commercial scale. Their dissimilarity makes the results of tests with different instruments not exactly comparable. It makes a considerable difference when and how the sounding body is held in relation to the ear tested. Below and in front of the orifice of the meatus is the direction in which the sound is heard furthest, because that is at right angles to the plane of the auricle.

Acoumeter and Watch.—In testing with the acoumeter or watch, it must be borne in mind that they are heard furthest when held at right angles to the plane of the auricle. Therefore, they should always be held in the same relative position to the auricle, which usually faces outward, a little forward, and downward. A very considerable difference is noted, depending on the way the sounding body is held. For instance, a watch held in the hollow of the hand with the broad surface towards the ear is heard much further than if the watch is suspended with its narrow side towards the ear. For these reasons, it is apparent that the sounding body should always be held in the same way and in the same relative position to the auricle.

The acoumeter and watch belong to the group of high-pitched sounds, and bear no constant relation to the capacity for speech perception. I have at present under treatment a civil service applicant, aged 25, who failed of appointment because the tick of a watch was not sufficiently well heard in one ear, but no defect of voice hearing was noticed. In another case, that of a man, 43 years old, watch, left ear, O. S. $\frac{5}{60}$, right ear, O. D. $\frac{60}{60}$; voice, left ear, O. S. $\frac{36}{40}$, right ear, O. D. $\frac{40}{40}$. A more common case is the man who can hear the mechanical sounds well, but has poor voice perception.

Variations in tests made with the acoumeter may arise from the differences in pitch, intensity and tone, between the various samples, and the careless way in which they are sounded. One watch cannot be compared with another. The same watch varies in pitch and intensity with the time of day and the cleanliness of its works, and different watches have a great variation.

Tuning fork tests bear no relation to the hearing for speech. One fork cannot be well compared with another, because of the varying properties of the different samples. Their curves of intensity are very variable and vary with differing initial impulses, which again are very difficult of regulation. Au-

thors do not agree on the curve of the intensity in relation to the time of vibration of tuning forks. Their relation is very complex. In using the tuning fork the interference zones must be borne in mind, and the same side of the fork should always be directed toward the meatus. In testing the length of perception, the distance must be constant. In some cases the after-impression continues longer than the sound can be heard; in others, the ear becomes exhausted when the sound is prolonged, but if it is interrupted it is perceived much longer. The fork should not be held opposite the meatus longer than is necessary to enable the patient to observe the presence or absence of sensation of sound. It should then be removed from the auditory zone for three or four seconds, the patient meantime being requested to say whether he still hears it or not. The fork should then be brought opposite the meatus again to see if he will hear it again.

To determine the auditory field, the scale should be divided into four zones, according to the Congressional Committee's report: Up to 64 V. D., from 64 to 256 V. D., from 256 again to 3,096 V. D., and lastly, those above 3,096 V. D. These zones correspond to the voice sounds, 1st, counter octave; 2d, the chest register; 3d, the vowel voice, and finally high-pitched consonants. The amplitude of the initial vibration of a tuning fork can be best measured by the method of Gradnigo. In forks of 256 V. D., the Gradnigo-Struycher method is best, and for 3,096 V. D., Schwiegelow's method is recommended. For testing the low limit, use 24, 32, and 48 V. D. The 16 V. D. has been discarded. With these low forks, care must be taken to make the patient distinguish between the flutter of the air and the note of the fork.

König's rods are recommended for testing sound perception for the scale above the range of the forks, and to determine the upper limit of perception. The same care should be used with these instruments as with the watch and acoumeter, though errors are more easily avoided. The chief error is that arising from the patient's mistaking the initial blow for the musical note of the rod.

Otologists have labored long for some ideally perfect method of testing the hearing, but until now all have failed.

What sound does the deaf patient wish to hear? Is it the tick of a watch, the click of an acoumeter, or the note of the tuning fork? No. Is it the human voice? It is the voice of his fellow beings which can alone bridge over that awful chasm of palpable silence or chaotic uproar which surrounds the deaf, parting him from acquaintances, friends, and family. On account of the imperfections of the voice tests other means are used: the watch, the acoumeter, the tuning fork, and the König rods. All these methods have difficulties in their application, and inaccuracies are apt to creep in, as I have mentioned. But all of these are used to determine whether the patient can hear in ordinary life the voice of his fellow man.

The fact is that the expert is forced to the use of mechanical tests because the voice tests are imperfect and unsatisfactory in some respects, but the inaccuracies and difficulties of these mechanical tests and above all the fact that in the end they do not determine whether or not the voice can be heard, oblige him to resort to the voice tests. He passes from one to the other and back, and neither is satisfactory, neither is accurate.

Realizing these difficulties, I have been experimenting for several years, to endeavor to make some instrument or machine which will secure accuracy and a definite standard, and at the same time determine whether the patient can hear the human voice. It seemed that a phonograph would provide the standard voice, that it could be controlled and would reproduce the same sound with the same intensity and pitch on all occasions.

I soon found many difficulties. There were no standard cylinders which were suitable. The instruments had to be adapted for my use. Before they could be of practical use, they had to be so arranged that the sound would not escape and thus allow it too much to reach the patient. This I have overcome by a sound-proof box. Then I had to get some device which would enable the operator at will to turn the sound on or off from either ear, without the knowledge of the patient. But most important of all, I had to devise a method by which the amount of sound reaching the patient could be accurately gauged and at the same time be under control of the expert.

I had many failures, but learned a little from each, until I finally secured a machine which has measurably, at least, cured most of these defects. I shall take great pleasure in showing it to you and having you test it. It certainly does provide a standard voice test which can be applied to either ear at the wish of the operator, without the knowledge of the patient, and it certainly provides a standard for the comparison of tests, equal to those used by ophthalmologists.

It would seem as if reasonable care taken in the making of the cylinders, instruments, and appliances, would make them all uniform, so that the tests made by one operator on one instrument, could be compared with those made by another operator or on a different instrument.

My machine allows the operator to determine accurately, the limit at which the patient is able to hear with sufficient distinctness to repeat the words spoken by the machine. Distance is no longer needed for the voice tests.

My acoumeter provides a sure method of detecting feigned deafness, an important matter in European countries. If the deafness feigned is anything short of absolute, the malingerer will be led into a trap. He is unable to give answers consistent with the varying positions of the graduating valve, combined with changes in the malingerer's valve, for he loses all idea of the intensity of the sound because distance is eliminated. When the malingerer feigns deafness in only one ear, the malingerer's valve, turning the sound on and off, rapidly alternating or simultaneously, distracts the patient; he cannot give replies consistent with deafness.

The previous methods of testing applied only to somewhat advanced degrees of deafness, which is a very serious loss to the patient, as all otologists know that the worst forms of progressive deafness, if taken in time, offer a comparatively encouraging prognosis.

My machine, besides allowing the detection of the slightest loss of hearing, gives a test for hyperacusis. It will test a hyperacoustic patient in a small office. It reduces extraneous sound to a minimum, doing away with the necessity of testing in a perfectly quiet office. This acoumeter is the best test for pitch and intensity of the alphabetical sounds which are equivalent to the logographic value of the letters. It is the best means of measuring the psychological factor in audition. This element enters into hearing to a very large extent, and forms one of the most important factors in determining the hearing effciency. Its true value has not been previously appreciated. The very marked increase of the hearing for polysyllables over disconnected monosyllables, and of a sentence over disconnected polysyllables, is due to this psychological factor, or the power of attention and quickness of guessing. In normal hearing,

much is inferred from the context. The accurate adjustment of this machine allows the accurate determination of this important factor in hearing, which has not been previously possible.

My acoumeter readily measures fatigue of the hearing mechanism. It is an acoustic masseur which has many advantages for very deaf people and others. I suggest the phonograph as the best and easiest means of giving deaf ears the exercise they require to prevent the rapid decrease of hearing consequent on disuse, and to prevent the psychological deafness which is such an important factor with very deaf ears, and which hinders the realization of improvement consequent on the alleviation of the cause. The good results of hearing exercises are best shown in deafness following suppuration of the ear, where, with artificial aids to hearing, the hearing will often increase over a long period of time. This improvement is due to the psychical element, becoming more and more favorable to sound perception, as well as to the mechanical improvement of the sound-conducting mechanism, and the functional exercise of the perceptive mechanism.

Summary.—The methods at present in use do not give adequate tests for the perception of the human voice, nor do they give results which can be compared. My Phonographic Acoumeter does all of these things, and more. It ivercomes the chief difficulties and inaccuracies formerly accompanying quantitative hearing tests. It gives a satisfaction and accuracy not hitherto attained. It furnishes a test with the human voice which does not vary and can be multiplied and repeated indefinitely. Unilateral as well as bilateral tests can be applied without doubt or error. Eyesight aids are eliminated. It furnishes a universal standard, whose records are always comparable. It furnishes a sure way of detecting all feigned deafness short of total bilateral deafness; and it is an ideal machine for furnishing acoustic exercise which has been recommended in the treatment of deafness.

Operation.—I prefer monosyllables to longer words for the phonographic test, because they have simpler and fewer sound effects giving definite results. Polysyllables give the patient opportunity to guess the sounds not distinctly heard, just as in a sentence a clever person easily supplies the words omitted. The operator is provided with a slip of paper on which the words of the records are printed to enable him to check the words as the patient repeats them after the phonograph.

The patient is instructed to repeat all he hears. His ear tubes are adjusted in his ears, the examiner taking his own tubes. The indicator is placed at 100° on the dial, and the phonograph is started. The operator slowly moves the indicator until the patient remarks that he hears, but does not understand, or repeats the words incoherently. Then the examiner, still moving the indicator, checks the words which the patient repeats correctly, on the word list previously provided. When the patient repeats at least seventy-five per cent. of the words correctly, out of ten or fifteen words, the scale is read and the test is completed. The reading of the scale gives the acuteness of hearing possessed by the patient. To get the absolute hearing, this number should be squared and multiplied by the percentage of words accurately repeated. A quick way of writing it is in the form of a fraction, the numerator being the reading of the scale, and the denominator the per cent. of words repeated. The ears are tested separately in the same way, by adjusting the three-way valve for the separate ears.

In order to test unilateral malingering, the indicator is placed at a point at which the malingerer hears readily by both ears together, and the operator quickly turning the malingerer's valve with his left hand, cuts off one or the other of the ears, but never both at once. At the same time he marks the words repeated correctly by the patient, with R for right, L for left, and O for both, or some similar symbols. The result will show conclusively, first, that the patient can hear; second, that hearing of the two ears bears a constant proportion each to the other, if there is no malingering. If the patient is a malingerer, the relative proportion will be irregular, for no malingerer can be quick enough to detect accurately every change in the volume and direction of the sound. The same procedure, combined with changes in the graduating valve, serves to detect feigned bilateral deafness.

THE RAPID BACTERIOLOGICAL DIAGNOSIS OF DIPHTHERIA.

By HENRY A. HIGLEY, M.D.,
BROOKLYN, N. Y.

By the "rapid bacteriological diagnosis of diphtheria" I desire to designate the identification of diphtheria bacilli by the means of stained smears made directly from the false membrane present in any given case. Since in this process no cultural methods or other bacteriological work proper are involved, the term "bacteriological diagnosis" is somewhat of a misnomer—the method being more fitly classed within the domain of clinical microscopy.

There are many reasons why the identification of diphtheria bacilli by the examination of stained smears made directly from the false membrane has never found any considerable use in the laboratory diagnosis of diphtheria. One of these has been the uncertainty of the procedure with the methods available. Those who have busied themselves most with the study of diphtheria bacilli have recognized at once its great variability in form (pleomorphism). Especially does this apply to the bacilli as they are obtained directly from the false membrane. * This being the case in smears made from such membrane, there is no staining technic which can be relied upon to bring out with regularity the essential characteristics of the microorganism as does Loeffler's alkaline methylene blue when the bacilli have been cultivated upon Loeffler's blood serum. Then again, the number of diphtheria bacilli present in true diphtheria membrane is subject to great variation. They may be present in large numbers or they may be rare. They may be practically the only microorganisms present, or the membrane may contain a large number of other microbes. It has seemed, therefore, that the failure to identify diphtheria bacilli in smears made from false membrane does not negative their presence in such membrane nearly so positively as when cultural methods are used and the bacilli, if sparingly present given a chance to grow and increase in number on suitable artificial media. For these reasons those most familiar with this subject will deny, by the utilization of present methods, the ability to identify, with any great regularity, diphtheria bacilli in stained smears made directly from false membrane or of negativing their presence in such membrane if not so found. This opinion is without doubt well taken. In many cases diphtheria

* By "diphtheria bacilli" here, as elsewhere, when the term is used in this article, is meant both the virulent and non-virulent varieties. It is not claimed that this method differentiates between virulent and non-virulent diphtheria bacilli, any more than does the cultural method on Loeffler's blood serum. It is claimed that it gives exactly the same differentiation as does the cultural method, and is practically instantaneous, saving from 12 to 24 hours over the cultural method.

bacilli are numerous in such smears. Loeffler's alkaline methylene blue and other stains bring out the characteristic morphology of the organism and a positive identification is possible. There are, however, a considerable number of instances in which this is not the case. In these, for one reason or another, an examination of the smears leads to an erroneous diagnosis. This can readily be proven by the results of cultures made simultaneously with the smears.

The use of the method here presented in the routine bacteriological diagnosis of diphtheria such as is being conducted by the health departments of our various municipalities is out of the question for at least two very potent reasons: (1) The difficulty and care necessary in making proper and reliable smears from false membrane is much greater than that which attends the making of cultures, so that smears made by practitioners in general would not be anywhere near as reliable for diagnostic work as the cultures which are now in general use. (2) Even with the use of this method, the time required for transmitting smears to public laboratories would equal that now consumed in the similar transportation of cultures, and all element of rapidity would be lost.

Therefore, in considering the "rapid bacteriological diagnosis of diphtheria" I do not wish in any way to be regarded as advocating its routine employment. My idea, rather, has been to place in the hands of special workers in clinical pathology, and who may from time to time desire it, a rapid method by which the diagnosis of diphtheria can be positively affirmed or denied. Not infrequently, instances arise in which such a rapid diagnosis is desirable or requested because of contingent circumstances. With this thought in view the present work was undertaken in order to determine:

(1) Whether a stain can be devised which will regularly bring out the characteristics of diphtheria bacilli and differentiate them from other bacilli so that they can always be recognized when present in smears made from false membrane.

(2) Whether any clinical method of making smears from false membrane can be practiced so that such smears will practically always contain diphtheria bacilli if these are present in the membrane—in other words, smears that can be relied upon for accurate diagnostic work.

In considering the identification of diphtheria bacilli in stained smears made directly from false membrane, certain characteristics common to diphtheria bacillil as found in such membrane require careful consideration. These are: (1) The unevenness of their contour; (2) their mode of division; (3) their grouping, and (4) the irregularity with which they stain.

Of these the first three are the most important. That is, they are the chief characteristics which serve to differentiate in smears made from false membrane diphtheria organisms from other bacilli which may be present. Especially may the first two be considered essential in this respect. The unevenness of contour of diphtheria bacilli as obtained directly from false membrane may perhaps without error, be called their most important differentiating characteristic. While the bacilli are almost always short, not very broad and of varying form, still these factors vary within tolerably wide limits so that upon the length, breadth, or form when taken singly or in combination, no positive identification can be made. If, however, within these limits of length, breadth and form, an unevenness of contour can with regularity be determined, a long stride is made toward their positive identification.

The mode of division of diphtheria bacilli is second in importance of their morphological differentiating characteristics. While their mode of division is variable, the most characteristic is that in which they become spindle-shaped just before division. The division takes place through the center of the rod. When it is completed there arise two somewhat elongated, uneven rods—the classical forms which have been described as characteristic of diphtheria bacilli obtained directly from false membrane. Frequently the bacillus turns on itself at the point of division so that when it is finished, the bacilli lie parallel. If this is continued, a characteristic "palisade-like" arrangement results. The grouping of diphtheria organisms in smears made directly from false membrane is characteristic, although without doubt it may be closely simulated by other bacilli. Groups of diphtheria bacilli which lie parallel or nearly so, are always to be found in smears made from true diphtheretic membrane. Very frequently they touch each other at their extremities. Taken in its entirety this grouping more nearly resembles the grouping of tubercle bacilli as seen in sputum than that of any other organism. Notwithstanding the characteristic features of this grouping of diphtheria bacilli experience has shown that of itself it cannot be relied upon as a differentiating factor. It is well known that diphtheria bacilli obtained directly from false membrane stain irregularly. They appear mottled, banded or contain distinct polar dots, according to the character of the stain employed, and the variety of diphtheria bacillus met with. It is a fact, however, that many other bacilli obtained from false membrane stain just as irregularly as do the diphtheria organisms, so that as a diagnostic feature, this characteristic loses its value excepting when taken in combination and careful consideration with the other characteristics mentioned.

If these characteristics, when taken conjointly, serve to differentiate diphtheria organisms from other bacilli present in false membranes, then any staining method which brings them out with regularity can be relied upon for the identification of said organisms when present in smears made from false membranes. In devising such a method, the ultimate end to be attained is the production of a picture in which the bacilli stand out in sharp relief upon the background. This background in smears made from false membrane usually consists of leucocytes, epithelial cells, and fibrin. It is at once evident that the desired result can never be accomplished with regularity by the use of a single stain. Frequently single stains, when applied to such smears, do bring out the bacilli and reveal their morphological characteristics in sharp relief, but at times this distinct definition of the microorganism is not obtained, being obscured by the deeply colored background. After experimentation with numerous double stains, it was found that sharp, distinct pictures were produced only by using very dilute double or contrast stains, and the following technic was decided upon:

Stains.—No. 1. Five drops of Kühnes carbolic methylene blue in seven cubic centimeters of tap water.

No. 2. Ten drops of carbol-fuchsin in seven cubic centimeters of tap water.

Method of Application.—(1) Fix smear by passing three times through the flame; (2) apply stain No. 1 for five seconds; (3) wash with tap water and dry with filter paper; (4) apply stain No. 2 for one minute; (5) wash, dry and mount in balsam.

It will be observed that in this method no decol-

orization is used between the application of stains No. 1 and No. 2, as is the custom in the employment of most contrast stains. The reason for this is that the use of any decolorizing method was found to act here with considerable irregularity. At times very satisfactory pictures by decolorization were produced, but not infrequently ones that were entirely useless.

There are five important points in the carrying out of this technic, each of which must be carefully observed: (1) The smears must be as thin as possible; (2) stain No. 1 must not be left on longer than five seconds; (3) stain No. 2 must not be left on longer than one minute, nor shorter than forty-five seconds; (4) the smear must be thoroughly washed and dried between the application of stains No. 1 and No. 2; (5) solutions No. 1 and No. 2 must be freshly prepared just before using. When thus stained the diphtheria bacilli appear as dark red or violet rods, irregularly stained, often containing polar dots. The unevenness of their contour and mode of division are regularly and distinctly brought out. Especially is this the case when the bacilli are found upon epithelial cells as a background, which practically always occurs. The epithelial cells are stained a bright red against which the color of the bacilli contrasts with great sharpness. Other microorganisms take varying tints and may appear of the same color as the diphtheria bacilli, so that upon color alone no differentiation is possible. The characteristic of the technic is that it regularly brings out the unevenness of contour of the diphtheria bacillus and with sharpness its mode of division so that it can be readily differentiated from other bacilli and no confusion be possible. The advantage of the method, and that which makes it valuable, is that the above described picture is regularly produced even with considerable variation in the thickness of the smear, although it is always desirable that the smear be as thinly spread as possible.

If, as I believe, diphtheria bacilli when present in smears made from false membrane, can be easily and regularly identified by the above described technic, the final problem in the "rapid bacteriological diagnosis of diphtheria" relates to the integrity of the smears. In other words, is it possible to make smears from false membrane so that these will always contain diphtheria bacilli if they are present in the membrane? It is at once evident that this question can only be correctly answered as the result of considerable experience. Smears must be made directly from false membrane, and at the same time cultures taken. If the results obtained from the smears regularly correspond to that from the cultures the smears may be regarded as reliable. After trying various methods the following was found to give regular and satisfactory results.

Making of the Smears.—The material which is used to make the smears is obtained from the false membrane by the means of a strong wire-looped needle—the wire being flattened by filing at its curved extremity so as to form a sort of curette. This loop is sterilized by heat in the flame, and when cool lightly passed over the false membrane, some of which will always adhere to the wire. A drop of distilled water is now placed upon a cover glass or slide and the smear made in this drop with the large looped needle upon which is the material. Three to five smears may be made with the material obtained, by the single application of the loop to the false membrane, by passing the loop from one cover glass or slide to another, each of which has upon it the drop of water. As a rule the second and third smears thus made are sufficiently thin, evenly spread and the most satisfactory for use, although, of course, this depends upon the amount of material which has been removed from the membrane, and is upon the wire loop.

During the past several months, by the above method, I have examined at the Kingston Avenue Hospital, New York City, 126 smears made directly from false membranes in cases of diphtheria and suspicious deposits in the throats of those sick with follicular tonsilitis and scarlet fever. Every smear examined was controlled by cultures simultaneously made. The diagnosis was made from the smear and later compared with the result of the culture. In all cases there was no difficulty in making a correct diagnosis from the smears. That is to say, whenever the smear showed diphtheria bacilli, the culture came out positive (diphtheria bacilli present), and whenever the smear showed no diphtheria bacilli the culture came out negative (no diphtheria bacilli present). From this experience I am forced to the conclusion that the method is a safe one, and that by its use when properly carried out, a rapid (15 minutes), and as sure a diagnosis as that given by cultural methods may be made by the examination of stained smears made directly from deposits or false membranes in cases which present themselves for the differential diagnosis of diphtheria.

The experience necessary for the successful use of the method is more than that possessed by the average clinical practitioner, and its employment is therefore advocated only for the special worker in clinical pathology who has had a fair experience in the morphological study of diphtheria bacilli.

In conclusion, it gives me great pleasure to acknowledge my indebtedness to Dr. William H. Park for aid and kind suggestions during this work.

227 Park Place.

THE BEST METHOD OF ADMINISTERING POTASSIUM IODIDE.*

By MAX HÜHNER, M.D.,

New York.

The best method of administering any drug is undoubtedly the one which most certainly accomplishes the purpose desired with the least possible undesirable effect. Applying this principle to potassium iodide, it necessarily follows that the method of administering will differ with the different purposes in view; thus, if we wish to give it for calcareous arteries for a long period, we would administer it differently than when the object is to produce a rapid impression, as in cerebral gumma, etc. Before discussing the different best methods for the different purposes, the following general principles will be found to apply to all methods alike.

(1) For therapeutic purposes potassium iodide should always be given in solution, well diluted, and if possible, never on an empty stomach.

For dilution, several things have been used. Milk is by far the best, for it not only disguises the taste more effectually, but also prevents, to a great degree, the disagreeable after effects of the drug. Another excellent vehicle is compound syrup of sarsaparilla. Mineral waters or ordinary pure water may also be used. The iodide of potassium should be diluted with about half a glass of the water or milk.

(2) It is essential to have a perfectly pure preparation. Pure iodide of potassium can be taken for a very long time and even in large doses without causing disturbances of the gastrointestinal canal.

* Prize Essay ("Clinical Excerpts").

Many of the bad effects of this drug are due to an impure preparation.

(3) It is necessary to observe strict cleanliness of the skin (daily baths), while taking iodide of potassium internally. By so doing, the disagreeable skin eruption may, to a large degree be prevented, the eruption being due to the decomposition of the iodine salt excreted with the perspiration by the fatty acids, setting free the iodine which acts as an irritant.

(4) As a practical matter it is preferable not to write for a 100 per cent. solution. Several years ago I wrote a prescription for potassium iodide to be given in drop doses gtt. i to represent gr. i of the drug, and was surprised to be informed by the druggist that it was impossible to make up a 100 per cent. solution. On consulting the late Dr. Charles Rice(head of the general drug department of Bellevue Hospital), he showed me that it was possible to make up such a solution, though with some difficulty. It became evident that most druggists would not take the necessary time and trouble, but would probably give a weaker solution. Where, therefore, accurate dosage is of importance, it is safer to prescribe a 50 per cent. solution, two drops to equal one grain of the drug.

(5) Iodide of potassium is incompatible with alkaloids and the ordinary soluble metallic salts.

While the patient is taking potassium iodide, calomel should not be dusted into the eye, for an effect may result similar to the application of a strong caustic on the mucous membrane. This point is fully discussed in all standard works.

(6) Small doses of the drug may produce symptoms of iodism while larger doses, in the same patient, may not have this effect.

(7) Potassium iodide should never be given in phthisis or when there is even a suspicion or tendency to phthisis. Its irritating effect upon the bronchial mucous membrane is a decided objection to its use in such cases. If, however, phthisis is associated with syphilis, it may be used to advantage.

Taking up next the more important conditions for which potassium iodide has been prescribed, I shall endeavor to indicate the best method of administering it in each condition.

Syphilis.—In a paper like the present, it is impossible to give anything like a complete discussion of the treatment of this disease, a bare outline only of the part played by iodide of potassium therein will be presented. Practically it ought never be given in the primary stage. In the secondary stage it should not be administered until the patient has had at least six months of treatment with mercury, preferably by inunctions. There is an exception, however, where some tertiary symptoms appear ahead of time (during the secondary stage), and threaten the integrity of some important organ, the brain, eye, etc. In such cases it is absolutely necessary to start with the drug at once, and run it up as rapidly as possible in a manner hereafter described. In the simple secondary lesions it is useless, but may prove beneficial in recurrence of secondary lesions. In an ideal case after six months' treatment with mercurial inunctions, I start the use of iodide of potassium with the well-known mixed treatment, using the formula:

℞

Hydrargyri iodidi rubri, ... gr. ss
Potassii iodidi, ... gr. cxxviij
Syr. sarsaparillæ co., ... ʒi
Aquæ q. s. ad..... ʒij
M. Sig. ʒi t. i. d. after meals, well diluted.

After a few weeks, however, I prefer to give the drug alone, and in solution in doses of ten to twenty-five grains t. i. d., giving mercury by inunction off and on for another six months at the same time. Throughout the treatment especial attention is, of course, given to the care of the mouth, teeth, gastrointestinal canal and skin.

When giving the drug in this way, and intending to keep up the same dose for a long time, I prefer not to order it in drop doses, but in solution ʒi = gr. x to gr. xxv, as follows:

℞

Potassii iodidi, ... ʒviii to ʒx
Syr. sarsaparillæ co., ... ʒi
Aquæ q. s. ad..... ʒiij
M. Sig. ʒi in half glass of milk or water t. i. d. after meals.

Again, when giving potassium iodide in this manner for its specific effect, and not to counteract any particular symptom, I stop at the first symptom of poisoning, wait a little while and then change the dose.

Very different, however, is the method of administering in tertiary syphilis, especially when some vital organ is threatened. Here I do not stop simply because some pustulation or rhinitis occurs, but continue right on in increasing doses till more serious symptoms make it impracticable. This is done for two reasons, first, by increasing the dose we may sometimes cause the symptoms of poisoning to disappear (a small dose may cause sypmtoms of poisoning, while a larger one may not); and second, even if the sypmtoms do not disappear, or even get worse, it is far more important to saturate the system as rapidly as possible with the drug, than to worry over a pustulation or rhinitis. In other words, we must endeavor to put as much iodide of potassium into the system as it can possibly stand, and also do it as rapidly as possible. My method consists in prescribing a 50 per cent. solution (gtt. ij = gr. i), and starting off with gtt. xx, increase gtt. ij at each dose as follows: First day 20 drops in the morning, 22 drops at noon, 24 drops at night; second day, 26 drops in the morning, 28 drops at noon, 30 drops at night; third day, 32 drops in the morning, and so on. Given in this way, ill effects rarely occur, and I have rarely had cause to stop it on account of unpleasant symptoms. At the same time the increase is rapid enough for ordinary purposes, although under extraordinary circumstances, we may increase by four drops instead of two at each dose. I have two patients at present, taking between 500 and 600 grains daily, without any annoying symptoms.

In an ideal case, after all symptoms of the disease have disappeared, and after two years of mercury and iodide of potassium given as above, I generally have the patient take the drug in the form of mixed treatment for another six or twelve months off and on, to make as certain as it is possible in syphilis that he is cured.

Cerebral Syphilis is benefited only in the early stages by absorption of the gumma or swelling of the intima. It cannot remove the scar or cause disappearance of the connective tissue or regeneration of the dead nerve cells. If no good results after two months' trial in large doses, together with inunction treatment, it should be discontinued, as it may do harm.

In all cases of cerebral or spinal cord tumor, with even a suspicion of syphilis, iodide of potassium (in large doses), should be given a trial. It may even do good in tumors not of syphilitic origin.

Locomotor Ataxia is here discussed because it is dependent upon syphilis to a certain degree. Iodide

of potassium has always held a prominent place in the treatment here, because in between 75 to 90 per cent. of all persons afflicted, there is a history of previous syphilitic infection. I have used the drug in various ways in combination with mercury and without it, after the administration of mercury and by itself, also in doses of 30 grains a day to 500 grains a day. I have occasionally seen an annoying symptom disappear under its use, and have often seen a general improvement in all the symptoms, and an apparent standstill of the disease, but I must confess that not only have I not seen anything resembling a cure, but in most cases the disease seems to run its course as badly with it as without it. On the whole, the better results were obtained by running up the drug to 100 grains three times a day, and keeping it up for a few weeks.

The peculiar nature of locomotor ataxia must be taken into consideration here. Although a history of syphilitic infection can be made out in such a large percentage of cases, yet neither clinically nor pathologically is it a syphilitic lesion; it often occurs in patients who have had the benefit of thorough antisyphilitic treatment, and may occur in persons where the primary sore was only suspicious, or even positively nonsyphilitic, not followed by secondary or tertiary symptoms, and producing healthy children. Considering all this, it is not surprising that iodide of potassium has not the brilliant effects it has in other and truly syphilitic lesions.

Chronic Endarteritis, whether syphilitic or not, is greatly improved by potassium iodide. It should be given in doses of gr. v to gr. xx, four times a day, for a long time, stopping off and on as soon as symptoms of iodism occur. Aneurysms are also best treated by this drug.

Chronic Endocarditis.—No matter what valves are diseased, if the arteries are contracted, iodide of potassium is an excellent remedy in doses of gr. v to gr. x three times a day, kept up for a long time. It may also be given in combination with digitalis, to modify the action of this drug on the arteries. It has absolutely no effect upon the heart except in very large doses, when the heart effects are due to the potassium part of the drug.

Asthma.—Potassium iodide has justly achieved a great reputation in this connection. The disease being dependent upon so many different causes, the cases must be carefully selected or we will often be sorely disappointed. If the asthmatic attacks are due to nasal polypi or other reflex nasal causes, the drug, by increasing the irritation of the nasal mucosa, can only do harm. The same applies if the attacks are due to a swelling of the mucus membrane of the bronchi. But if due to a spasm of the arterioles as shown by contracted radial arteries, excellent results will follow its administration. My method in such cases has been, first to give large doses of nitroglycerin, which acts more rapidly than potassium iodide, and then potassium iodide in doses from gr. x to gr. xx t. i. d. These doses if kept up for a long time, will produce a permanent cure in quite a few cases. In a still larger number of cases, a temporary disappearance of all symptoms results.

Chronic Bronchitis, if secondary to chronic endocarditis or endarteritis, is greatly benefited by doses of gr. v to gr. x three times a day, given for a long time.

Chronic Nephritis, no matter of what variety, if accompanied by contracted arteries, is benefited by small doses.

Lead Poisoning.—Here the drug must be given in small doses (gr. v-x t. i. d.) for a long time. It must not be given up if the symptoms get worse, that being often due to the liberation of the lead and its circulation through the system. For the same reason it must not be given in too large doses or too rapidly, else the lead may be eliminated too rapidly and cause cerebral symptoms. In anemic persons it may be combined with iron.

Rheumatism.—It is useless in the acute and also in most cases of muscular rheumatism. In the severer forms of the latter, it often does good when combined with gelsemium. In chronic rheumatism it often does good after the salicylates have failed. It may also be given in combination with sodium salicylate and colchicum, as in the following dispensary formula:

℞

Potassii iodidi,
Sodii salicylatis, ...āa ℥ij
Vini colchici seminis, ... ℥ij
Aquæ q. s. ad..... ℥iv
M. Sig.: ℥ss q. 4 h.

Gout is only favorably affected by the drug if associated with rheumatism.

Neuralgia, especially if dependent upon syphilis, is often cured thereby.

In administering the drug to children, two methods have been employed, the indirect and the direct. The indirect consists in giving the drug to the mother or wet nurse, in the hope that it be excreted in the milk, and the nursing child obtain it in this way.

But while it is true that after prolonged administration to the mother, its physiological and therapeutical effects may be noticed in the child, including symptoms of poisoning, and presence of iodine in the urine, it must nevertheless be admitted that anything like exact dosage or even certainty of action cannot be relied upon.

In the direct method it must not be forgotten that in children the symptoms of poisoning are chiefly of the gastrointestinal variety. Children stand relatively much larger doses than adults, and no limitations of Young's or Cowling's rules of dosage are applicable. The drug is best given well diluted and very frequently in small doses rather than infrequently in large doses, thus it is better to give ¼ grain every hour than one grain every four hours. Its chief use is in hereditary syphilis and in meningitis, whether syphilitic or not. In both these conditions it must be given in very large doses. In this way it is possible for a six-months-old child to take as much as gr. xv to gr. xxx in 24 hours, for a long time without inconvenience. Larger children may take as much as ℥ij in 24 hours. In simple acute non-suppurative adenitis I have given a one-year-old child as much as gr. xv in 24 hours, for a long while, without bad effects, and with complete absorption of the glands. Of course, hygienic treatment was not neglected as well as removal of all possible exciting causes.

A very convenient way of giving the drug to very young infants is to tell the mother or nurse how much of the drug (in solution) the child is to take in 24 hours, and dissolve this in 24 teaspoonfuls of water, to have the child take one teaspoonful every hour while awake, and two or three teaspoonfuls upon awakening after a two or three hours' sleep.

It is, therefore, evident that the method of administering potassium iodide is not uniform, but varies with the different conditions for which it is given, except for the general rules enunciated at the commencement of this paper.

64 East Fifty-Eighth Street.

A NEW REMEDY FOR ULCERATIVE PROCESSES, ACUTE AND CHRONIC, INCLUDING PULMONARY TUBERCULOSIS.

By HUBBARD W. MITCHELL, M.D.,

NEW YORK.

The difficulty of successfully treating ulcerative processes, either acute or chronic, is too well known to admit of comment. The severe ulcerations of the cervix uteri, especially those cases complicated with lacerations of long standing, render treatment slow and tedious. Ulcerations of the lower extremities, either traumatic, varicose, or syphilitic, in old, feeble, or debilitated subjects, render any form of treatment very difficult. Suppurating buboes often defy all attempts to cure. The ulcerative process of the lung tissue known as pulmonary tuberculosis has been very rebellious to any known mode of treatment.

The obstinate nature of this class of cases to all curative measures, and the earnest desire to find some means for a certain and more speedy cure, led me some years ago to begin a series of chemical experiments, to discover if possible some medicinal agent that possessed the power to modify or heal ulcerative processes.

The result of these experiments—extending as they did over a protracted period of time—was the discovery of an antiseptic fluid, having rather remarkable healing properties on this particular class of cases of ulceration. The practical chemist who aided me in these experiments gave the preparation the chemical name of a "solution of chlorobromide of sodium." It has since been more generally known as "Mitchell's fluid."

This fluid is prepared as follows: To a convenient quantity of water add 3 per cent. sodium chloride, 0.1 per cent bromine, and 0.5 per cent. hydrochloric acid (C. P.). Subject this mixture to the action of an electrical current until such chemical action has taken place within the mixture as to convert all free bromine into a compound with the other elements present. The length of time necessary for this depends upon the amount of fluid acted upon and the strength of the current used. The resulting fluid is pale amber in color, with a strong odor of chlorine, a slightly acid taste, and a sp. gr. 1022. It must be kept in amber colored bottles, in a cool place, and tightly corked.

The preparation once discovered and its chemical composition known, it became necessary to test it upon a considerable number of ulcerative cases, to determine positively if it really did possess the special properties ascribed to it, since theory, not sustained by practice, is of no value. A course of experimental work was at once begun.

Through the courtesy and very practical help of several of my medical friends on the visiting staff of the City Hospital, Blackwell's Island, I was enabled to test this fluid on a large number of patients in that institution.

The results were certainly very satisfactory. Chronic ulcers of the leg, regarded as well-nigh hopeless, were cured. Suppurative buboes, which hitherto had resisted all modes of treatment, healed kindly and speedily. Cases of ulcerative cervical endometritis of a chronic and severe character quickly disappeared under the direct local application of this fluid.

As the results of the external application of Mitchell's fluid had proved so favorable, it was then determined to try it internally upon that class of ulcerative processes of the lung known as pulmonary tuberculosis. Accordingly a number of such cases were selected—all severe and chronic—and treated by giving the fluid internally in one ounce doses before each meal and at bedtime. It was thought that if the fluid was taken when the stomach was perfectly empty, it would be quickly absorbed and carried practically unchanged by the blood current into the lungs, and there be brought into contact with the ulcerated lung tissue. These experiments were continued rather more than a year, and upon about one hundred cases.

The results seemed satisfactory, and upon the conclusions so reached a paper was prepared and read before the New York County Medical Association, in November, 1895, setting forth the facts as far as they had been discovered up to that time. The claims then made for the fluid were based simply and only upon the results obtained from its use in the class of ulcerative processes above enumerated.

Greater experience and more accurately conducted experiments soon demonstrated the fact that the chemical composition of the fluid needed some modification, and, moreover, one or two years was not time enough to determine the fact whether it had any real and lasting benefit in so grave a disease as consumption. So many extravagant, vague, and untenable claims have been made in the treatment of this disease, and so many new "cures" offered, that it is with extreme reluctance, and after long hesitation, that this fluid is again brought to the attention of the profession. It is now believed to stand upon a sound and scientific chemical basis.

The chemical name is the same as it formerly was, viz., a "solution of chlorobromide of sodium," and it is prepared after the formula above given. The present experience is based upon its use in nearly one thousand cases.

It seems to possess a peculiarly healing power in pulmonary tuberculosis, which a very rigid and practical experience has demonstrated. In treating this disease, it should be remembered that it is distinctively an ulcerative process going on in the delicate spongy tissue of the lungs; that this process goes on until it destroys the lung tissue to an extent that causes death, if unchecked; that the ulcerative process seems to give rise to a poisonous principle in the blood, which produces general anemia and the train of depressing symptoms due to blood impoverishment.

To treat this form of disease successfully, two things must be accomplished, namely, (1) a checking of the ulcerative process, and (2) a restoration of the general health.

As to the first: Mitchell's fluid seems to have the power to check such ulcerative processes and, if the disease is not too far advanced when first seen, ultimately to effect a cure. It must be given in free doses, for a considerable period of time, from 1 to 1½ ounces clear four times daily, *i. e.* before each meal and at bedtime. It is imperative to have the stomach completely empty when the fluid is taken.

As the fluid has a hydrochloric acid reaction, and as the gastric juice has the same chemical reaction, it can be taken a long time without injury, but rather with a positive benefit to the appetite and the digestion. It has besides an antiseptic influence upon the poison-laden blood, as is shown by a gradual improvement in the symptoms.

In severe cases of pulmonary tuberculosis—not those cases with contracted and deformed chest walls, or those with a taint of hereditary syphilis, and made worse by a vicious mode of life, which generally end fatally despite the most careful treatment—there is often a condition of depression, loss of appetite, and debility, that calls for a tonic specially adapted to it. A tablet of strychnine 1-60

grain, once or twice daily is excellent for this purpose.

The following formulæ have been found to possess particular value:

℞ Tinct. Gentian. Comp..... 5iv
Acidi Sulph. Aromatici..... 3iii
Syrupi Simplicis..... 3iv
Misce et signa: Spoonful after each meal.

℞ Tinct. Gentian. Comp..... 5iv
Acidi Phosphorici Diluti..... 5iv
Syrupi Simplicis..... 3iv
Misce et signa: Spoonful after each meal.

One of these tonic preparations may be given in conjunction with Mitchell's fluid, and continued until the general condition is better, when it may be reduced in quantity, and finally withdrawn. The fluid will then be a sufficient amount of medication.

Opium is rarely required. Alcohol is, as a rule, contraindicated. Tobacco should be prohibited during treatment. As to the second indication, viz., to restore the general health. As the malady under discussion is an ulcerative process of the lung tissue, giving rise to a peculiar toxic principle which severely depresses the vital powers, it follows that the impaired general health must be restored to a normal standard by proper, rational and physiological means.

Next then, in importance to the administration of proper medicines, is the question of *nutrition*.

This function is usually much impaired. To restore it is often a difficult matter. Those articles of diet having the greatest amount of nutriment must be selected. Rich soups, steaks, chops, yolks of soft boiled eggs well seasoned, good bread and butter, potatoes, oysters, tea and coffee with cream and sugar, given as needed, and chosen carefully, are among the best. As the appetite is poor, and often capricious, it must be carefully restored—never forced. Personal comfort must be preserved.

The air of the room, both by day and night, must be kept fresh and pure, but always at a comfortable temperature.

In mild cases the patients can follow the above method of treatment at their own homes, and still pursue their daily avocations. The attending physician can instruct them as to sanitary rules to be observed.

Climate plays a less important part than was formerly supposed. That of New York City is very favorable, and the necessity of sending patients away from their own homes, to health resorts and sanatoria, is now, I believe, generally regarded as less important.

The modern method of instructing patients how to observe and follow sanitary rules as to their own care, and for the prevention of communicating the disease to others, is of untold value.

To cure a case of pulmonary tuberculosis—even a mild case—requires long and persistent treatment, and a faithful observance on the part of the patient of all rules laid down for his benefit. But if the mode of treatment above outlined be carefully and diligently followed, sufferers with pulmonary tuberculosis can be reasonably sure of being cured of their trouble, and with a fair amount of bodily comfort.

747 Madison Avenue.

Fever and Feverishness in Children.—Charles W. Chapman believes that there is no surer road to professional success than that opened up by the knowledge of everyday children's diseases. Great care should be given to the diagnosing of disease in children, no matter how trivial the complaint may appear to be. Probably every illness has at some time been attributed to teething. The nervous system and the digestive system are both undergoing developmental changes at the time of dentition, and are during this period peculiarly sensitive to all forms of irritation. It is not strange that fever, convulsions and diarrhea are commonly found in infants who are cutting their teeth. Any one of these symptoms may be caused by a chill, or by an error in diet. Acute illnesses, absolutely unconnected with teething, may occur during the period of dentition, and much valuable time will be lost if the physician's attention is centered entirely on the child's gums. A very common cause of fever in children is tonsillitis. The throat should always be examined in every case of feverishness. For in this way the presence of one of the exanthemata and inflammation of the pharynx may be detected. The detection of tonsillitis is especially valuable in relation to the presence of a rheumatic tendency. The writer has observed many cases of organic heart disease that have had their rheumatic history limited to attacks of tonsillitis. It is most important to keep the throat, and especially the tonsils, in a healthy state. Unhealthy tonsils offer an open gateway to diphtheria, rheumatic fever, scarlet fever, and so on. Gastro-intestinal irritation is a frequent cause of feverishness. Too great care cannot be given to the supervision of children's food. Many cases of illness have their origin at children's parties. The effect on the digestive organs of insufficient protection of the abdomen and legs from cold is well known. The physician should always be on the lookout in cases of feverishness for the presence of bronchopneumonia and pneumonia. Very careful examinations of the chest are often necessary for the detection of these troubles, which may be limited to small areas. Every effort should be made to discover the cause of the pyrexia. If a dietetic error is found, a mercurial aperient suitable to the age of the child is indicated. It may be said that, in general, convalescence will be assisted by the administration of gr. 2-5 of sodium bicarbonate with rhubarb, if the tongue has not cleaned, or gr. 2-3 of carbonate of bismuth when gastric irritability and redness of the tongue are present.—*The British Journal of Children's Diseases.*

The Alexander-Adams Operation.—Fehling does not agree with those surgeons who advocate free opening of the inguinal canal in this operation. He ascribes most of the untoward sequelæ sometimes observed to this method of procedure, and says that he has operated on one hundred and six cases in the last three and a half years without a single complication and with only 4.4 per cent. of relapses. The last one hundred operations were performed as follows: A curved incision is made from a point half way between the anterior superior spine of the ilium and symphysis of the one side to the other, passing over each tuberculum pubis. The outer part of each incision is deepened until the fascia of the external oblique is reached and the columns of the ring are defined. The ligament is then sought for by blunt dissection, taking care to isolate the ilioinguinal nerve. The ligament is then seized with a small clamp and drawn down to its peritoneal investment. The ligament itself will stand considerabe traction, the cases in which it is said to have torn are usually due to mistaking artefacts from the fascia for it. Following this method, the ligament may always be found, and injuries to other structures are very rare.—*Zentralblatt für Gynäkologie.*

Iron Ring from Human Blood.—It is said that M. Barruel, head of the chemical laboratories of Paris, wears on his finger what is probably the most remarkable ring in the world. Having in his time practised much phlebotomy on human subjects, M. Barruel has systematically extracted chemically the iron from the blood collected. The metal was kept in the shape of minute globules or pearls, and at last the idea occurred to him to have these all welded together in ring form.—*London Globe.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, April 1, 1905.

HOT BATHS IN THE TREATMENT OF CEREBROSPINAL MENINGITIS.

THE inefficacy of our present methods of treatment of cerebrospinal meningitis is a fact which must be mournfully acknowledged, for a perfect recovery from a sharp attack of this disease is so rare as to be worthy of record. Even alleviative measures seem to be of little use, and it must be admitted that until much more is definitely known of the malady from all points of view, physicians must confess themselves beaten in their fight against its spread. It is to be hoped that the Commission recently appointed in New York City with the object of unravelling some of its moot points will be successful in their quest. A few features in connection with the disease are fairly well understood—that it usually attacks children; that it is most prevalent among the poor and in those districts in which dirt and overcrowding exist, and that it is probably infectious. As to whether severe weather exerts any influence on the origin and spread of the affection is a point upon which authorities are not unanimous.

There are two modes of treatment, not to mention the recently suggested use of diphtheria antitoxin, which stand out prominently, although testimony as to their merits is inconclusive and statistics bearing on the subject are meagre to a degree. The first of these is lumbar puncture, and the other method of treatment is by means of hot baths.

In Allbutt's "System of Medicine" no mention is made of the hot bath treatment of cerebrospinal meningitis, although bleeding, cold applications, emetics, and mercurialization are all referred to more or less approvingly. Netter, in the "Twentieth Century Practice of Medicine," in a short notice of hot baths as a remedy for the disease, highly lauds the method. He states that such baths are usually repeated four or five times a day, the immersion being prolonged from one-half to three-quarters of an hour.

The *Albany Medical Annals* for March, 1905, is given up to a consideration of cerebrospinal meningitis from various aspects, the papers being contributed by men well qualified to pass authoritative opinions. Dr. Stockton of Buffalo discusses treatment and reviews at some length the literature dealing with hot baths. Some of the writers he quotes are highly eulogistic of this mode of treatment, some are more reserved in their expressions of commendation, while some are openly sceptical as to its value. On the whole, however, the majority are in favor of this form of treatment. Aufrecht, in 1894, initiated the hot bath as a means of treating cerebrospinal meningitis, and announced excellent results. By far the most enthusiastic testimony, however, as to their beneficial effects comes from Russia. According to *Modern Medicine* for October, 1904, M. Rogansky has recently published in the *Meditsinskoye Obozreniye* the remarkable results of his employment of Aufrecht's method for a period of five years. During this time fifty-one patients were under treatment in the women's wards. Hot baths at 104° F. were administered for fifteen or twenty minutes once or twice a day. The precaution was taken to apply an ice-bag to the head of the patient during the bath. In his paper the author particularly emphasizes the wonderful effect of hot baths on patients admitted in a subdelirious condition. Most of them recovered consciousness as a result of the first bath, even patients who had been delirious for two or three days. In a few cases consciousness was not restored until after the third bath, but in those cases in which consciousness did not return immediately, restlessness and delirium were diminished or disappeared entirely. Pain was always relieved, even in fatal cases, but the influence of the treatment on temperature, vomiting, and cervical rigidity was not so marked. Of these fifty-one patients thirty-four were cured and seventeen died, giving a mortality of 33 per cent. In the men's ward, with fifty patients upon whom the method was not tried, forty deaths occurred, a mortality of 80 per cent.

A comparison of these figures offers testimony to the efficacy of the treatment, and it suggests the expediency of adopting the hot-bath treatment of cerebrospinal meningitis as a routine measure. At any rate, the treatment is worthy of close investigation at the hands of physicians in the epidemic now raging in New York and elsewhere in the country.

DR. REED'S INDISCRETION.

DR. C. A. L. REED of Cincinnati was recently sent to Panama on a non-professional mission to assess the value of certain real estate acquired there by our Government. But as he was a prominent physician and one presumably well qualified to judge of the existing sanitary conditions on the isthmus, the Secretary of War requested him to make an unofficial report on these matters. Dr. Reed accepted the invitation with alacrity, and made a report in which he scored roundly the bungling officiousness of the members of the Canal Commission, and of one member in particular whose sole aim, to judge by his acts, seemed to be to defeat the chief sanitary officer's well-directed efforts to render the canal zone a fit place for human habitation. Instead of giving Colonel Gorgas, the chief sanitary officer, a free hand to institute the measures which he had found to be effective in Havana, under the intelligent compliance of Governor Wood, the commission hampered him in every way. A lay board of health was constituted and all initiative was taken away from the only man among them who knows anything of sanitary matters.

The chief sanitary officer, whose department the medical profession had asked to be made largely autonomous, and which the President himself had obviously intended to be so, became, by action of the commission, subordinated to the governor of the zone; to the chief disbursing officer; to the chief of the bureau of material and supplies; to Mr. Grun-

sky; to the commission; to the Secretary of War; to the President; subordinated, in fact, in the seventh degree from the original source of authority, and this, says Dr. Reed, is the state of affairs on the isthmus to-day. "If the superintendent of the Ancon Hospital makes a requisition for supplies, he must take it for approval to the chief sanitary officer; then to the governor of the zone; then to the chief disbursing officer; whence it goes to the commission at Washington; then to Mr. Grunsky [as committeeman of the health department]; then back to the commission; then, if allowed, bids are advertised for; awards are made; the requisition is filled under the supervision of a purchasing agent notoriously ignorant of the character and quality of medical and surgical supplies; the material is shipped to the isthmus; consigned to the chief of the bureau of material and supplies, who notifies the disbursing officer, who notifies Colonel Gorgas, who in turn notifies the superintendent, who applies to the quartermaster for transportation, and so much of the stuff as in the judgment of, first, the governor, next the chief disbursing officer, next the commission, next and more particularly Mr. Grunsky, ought to be allowed to the superintendent of the hospital, finally arrives or does not arrive at its destination."

Dr. Reed quotes instances showing how requests by the sanitary department for necessaries have been treated. For instance, "doors and windows for the hospital at Culebra were asked for in January, but are not in place. Materials for disinfection work were asked for last September; the commision cut the estimate down to one-fourth, and sent the material in small lots from time to time. Before Colonel Gorgas went to the isthmus he laid before the commission a plan of campaign which embraced (1) the installation of a sewer system in the cities of Colon and Panama; (2) the installation of water supply in those cities; (3) the cleaning of the streets, including the disposal of garbage and night soil; (4) general sanitation of houses, including their cleaning and fumigation and the drainage of neighboring pools, the abolition of water barrels and cisterns and other places for the propagation of the yellow-fever mosquito; (5) the prompt isolation of all cases of yellow fever. It was not until after four or five months had elapsed, however, and only after progressive development of yellow fever, that Colonel Gorgas was permitted by the commission to assume the sanitary control of the two cities—one of which, Panama, had by this time become very generally infected." The report states that the responsibility for the present existence of yellow fever on the isthmus can be placed nowhere else than on the canal commission, more especially on Mr. Grunsky. It also states that the campaign against malaria has been thwarted by the commission, that many employees are sick with malaria, and that both nurses and attendants are frequently victims of the disease.

The report from which we have quoted can hardly be called a temperate one, but it is distinctly a truthful one, and it could be corroborated, if corroboration were necessary, by numbers of the physicians who took part in the Pan-American Medical Congress recently held at Panama, although they had far less opportunity to get at the real facts than had Dr. Reed. Had the writer of the report been content to give it to Secretary Taft and say no more about it, the President might or might not have acted upon it; but this uncertainty did not suit Dr. Reed. So he published it in full in the *Journal of the American Medical Association* of March 11, and it thus became public property, much to the disgust of the authorities at Washington. How deep was their displeasure is evidenced in the rebuke contained in the President's letter to Secretary Taft acknowledging the receipt of the report. He says: "Dr. Reed has not displayed in this report the qualities of temperament or the power of accurate judicial observation needed to make a report valuable to the Government. . . . When he assumed to make a report on sanitary conditions at your request as Secretary of War he was under obligation to speak with care and justice on so important a subject and to observe the proprieties as to its publication." Despite these stern words of reproof, one cannot but feel that, were the conditions reversed, the intemperateness of the report and the impropriety of its publication would have been pronounced entirely characteristic of the strenuous Mr. Roosevelt. Perhaps he was moved to indignation less by the publication of the report than by the impertinence of its concluding sentence, which was as follows: "I have the honor not only to submit the suggestion, but really to urge that the time has arrived when the President ought to redeem his word and ask for the resignation of the commission."

Tact and diplomacy of the orthodox kind are very necessary as a general rule of action in public as well as in private affairs, but on certain rare occasions more good can be accomplished by blurting out what one thinks without regard to the amenities, and this was possibly one of these occasions. As physicians, we are not concerned, except in a general way, as all good citizens should be, with the ineptitude of the Panama Canal Commission, but we are very deeply concerned with the action of the commission in thwarting Colonel Gorgas's efforts to save life on the isthmus. If Dr. Reed's impropriety awakens the public mind to the imminent danger of failure of the all-essential work of sanitation of the Canal Zone, (it has possibly borne fruit already in the forced resignation of all the members of the committee, just announced), his indiscretion will be condoned and approved by those who have the wit to see that the canal will never be dug by dead men, or even by sick men.

Puerperal Fever in London Lying-in Hospitals.

The March number of *The Practitioner* is devoted to a consideration of puerperal sepsis from many points of view. All the articles contained therein are written by acknowledged authorities on the subject of midwifery, and thus there has been gathered some extremely valuable information. Dr. William J. Gow writes on puerperal fever in London lying-in hospitals. Before antiseptics came into use the causation of puerperal sepsis was not understood, and in consequence the condition was not treated intelligently or effectively. Within a comparatively few years a great change has come over the situation, so far as the treatment of childbed fever is concerned, and now the suffering woman has had brought to her aid all the resources of science. Perhaps, although it may seem boastful to say so, nowhere in the world is the hospital treatment of parturient women carried out so thoroughly and effectively in all its details as in this country, and especially is this the case in New York. Here most of the maternity institutions are new, built for the express purpose, and equipped and furnished throughout

with every convenience that expert knowledge can conceive. In London the majority of the lying-in hospitals are old buildings, containing small rooms, so that however skillful the accoucheur may be, he is handicapped to a certain extent. Taking everything into consideration, the results obtained in the hospitals for lying-in women in London and other large cities of Great Britain are remarkably good. Needless to say, precautions of the most rigid nature are taken to prevent infection. The following rules, for example, are followed in Queen Charlotte's Lying-in Hospital: "1. Keep the nails short and remove all rings. Turn up the sleeves. 2. Wash the hands thoroughly in soap and water, and scrub with a nail brush. 3. Rinse the hands in clean water, but do not dry them with a towel. 4. Immerse the hands immediately in 1-1,000 perchloride of mercury for one minute, at the same time scrubbing them with a nail brush. 5. Lubricate the examining finger with vaselin immersed in 1-1,000 perchloride of mercury. 6. Hold up the examining hand, in order that it may not come into contact with anything until the moment for the examination arrives. 7. After the examination has been completed, wash the hands thoroughly in soap and water." After the child is born, no undue efforts are made to accelerate the expulsion of the after-birth. A douche is not given as a routine practice, but is generally employed if the labor has been instrumental. In such cases a quart of 1-4,000 perchloride of mercury is given, followed by a pint of plain hot water. Perineal and other tears are carefully sutured. The entire course of action in this and other London maternity hospitals is based upon the conviction that excessive care during labor is the surest means of obviating the danger of puerperal sepsis, and therefore every possible precautionary measure should be taken. Instruments are employed only when absolutely necessary, as it is believed that they are sometimes the cause of puerperal septicemia.

The End of the Coroner System.

There is a bill before the New York Legislature to abolish the antiquated coroner system, and it is announced that there will be a hearing before the committee in regard to it. It is difficult to conceive of any reason why this system should be retained, but presumably there will be some voices raised in opposition to the bill. Both houses of the Legislature passed a similar bill a year ago, and Mayor McClellan made one of his mistakes in vetoing it. Whether he has seen a new light since or whether he will again veto it, if passed, we are not in position to say; but we do not think it probable that the bill will be again vetoed. Mr. McClellan is of the type of President Roosevelt in that he tries to do right, but is forced to acknowledge his political limitations, and if he cannot do what seems to him best he will do the best he can under the conditions that beset him. Perhaps these conditions are different from what they were last year, but if they are not and he still feels the necessity of rejecting the bill, the Legislature will be able to pass it again over his veto by a mere majority vote. There is every reason to hope, therefore, that the end of the pernicious coroner system in this city is within sight.

The Rhodes Scholars at Oxford.—It is gratifying to learn the American Rhodes scholars are carrying all before them at Oxford. A young man from Cornell has won both the half and the one-mile races, a Bowdoin boy the weight and hammer contest, while a youth from South Dakota is credited with a treble victory—high jump, long jump, and hurdles.—*The Globe.*

News of the Week.

The Osteopathic Bill, now before the New York State Legislature, has been reported favorably by the Senate Judiciary Committee. The medical profession throughout the State should make a determined effort to bring about the defeat of this utterly indefensible and pernicious measure. If every physician would take it upon himself to write a personal letter to the Senator and Assemblyman from his district, protesting in the strongest terms at his command against the bill, the members of the Legislature might be led to realize that there is something to be reckoned with in professional opinion and they would hesitate to nullify our State license law by measures such as this.

Cerebrospinal Meningitis.—During the week ending March 25 there were fifty-seven deaths in the borough of Manhattan resulting from cerebrospinal fever, and in all boroughs the deaths directly attributable to that disease reached eighty-five. In the week ending March 25, 1904, cerebrospinal meningitis carried off only ten victims in Manhattan, and fourteen in the whole of Greater New York. At a meeting held last week, the meningitis commission formed itself into two sub-committees, one to investigate the bacteriological side, and the other the clinical side of the disease. Forms have been drawn up which will be sent to the hospitals in this and other cities for the purpose of collecting all possible data bearing on the question of the transmission of the disease. Dr. T. Mitchell Prudden has been retained as consulting bacteriologist.

Typhoid Fever in Philadelphia.—Melting ice and snow and spring rains are contributing their share toward the increased prevalence of typhoid fever in Philadelphia, the number of cases reported for the week ended March 25 being 307, with 17 deaths. Of the entire number 199 are from wards receiving their supply of water directly from the Delaware river, while only 4 are from wards receiving filtered water. In the absence of filtration, the Bureau of Health continues to advise boiling all water used for domestic purposes.

N. S. Davis Memorial Tablet.—A memorial tablet for the late Dr. N. S. Davis was presented by the senior medical class of the Northwestern University Medical School, March 24, in Davis Hall. The tablet bears the inscription: "Good and great, he maketh the earth wholesome." Addresses were delivered by Drs. E. Wyllys Andrews, E. G. Dudley, W. O. Krohn, George W. Webster, and Dean Holgate of the University.

Dr. Matas' Silver Jubilee.—On March 19, the medical and personal friends of Dr. Rudolph Matas of New Orleans presented him with a silver service of 125 pieces and a silver loving cup in celebration of the twenty-fifth anniversary of his entrance into the medical profession. The presentation was made by Dr. Chaillé, Dean of the Medical Faculty of Tulane University, and was seconded by Rabbi I. L. Leucht of the Touro Synagogue, in the presence of between thirty and forty of the donors.

Formation of a Business Bureau by the Chicago Medical Society.—This society contemplates organizing a business bureau for the transaction of business. The reasons why a bureau should be established are set forth by those advocating the measure, as follows: (1) To do collections at as moderate a charge as possible, which could be done if all the members in good standing patronize the bureau; smallness of the percentage charge would be an inducement to put bills in the bureau earlier for collection than is now done with independent

agencies. (2) To probate bills at the least possible cost. (3) In cases of sickness or death of the members of the profession, the bureau would make up his books, collect and bank the money, thereby giving great aid to the family; this same may be said of men desiring to go on much needed vacations for recuperation, or for scientific advancement. (4) The bureau generally would, for a comparatively small charge, transact any business whatever pertaining to its members in good standing, and thereby avoid much of the hardship that comes from the unbusinesslike methods of the modern practitioner for the need of a place of his own to take the necessary interest in his affairs. The society would have at its disposal an office that will be able to do much other work, as the tabulation of midwives, the investigation of the unprofessional conduction of many institutions, the compilation of an official directory, and many other things for the best interests of the profession that to-day are neglected for want of an office under its control.

Suit Against a Surgeon.—Suit has been brought against a prominent ophthalmic surgeon of this city recover $20,000 damages for alleged negligence in performing an operation for myopia. Four operations were performed in all, and it is asserted that in consequence of these the patient, who is a trained nurse, was totally blind for three months and that at present her sight is blurred and imperfect.

Trachoma Among Japanese Immigrants.—It is reported that a notable increase in the number of Japanese immigrants suffering from trachoma has been observed of late. Forty-nine new arrivals at Seattle have already been reported on this account. If an alien arriving on one of the Japanese liners has trachoma and it can be proven that his condition could have been ascertained before he left the Orient, a fine of $100 is assessed against the steamship company.

Cincinnati Academy of Medicine.—At a regular meeting, March 20, Dr. Frank Fee presented specimens of a lung in a marked condition of anthracosis. Dr. H. J. Whitacre presented a case of a plastic operation to replace a nose destroyed by a shotgun. The bone with its integument being obtained from the sternum. Dr. Robert Carothers read the paper of the evening on Tetanus. He reported five cases, all with a fatal result.

Ohio Soldiers' and Sailors' Orphans' Home.—Drs. Frederick Forchheimer, L. E. Russel, and Robt. Sattler have been appointed consulting physicians to the above institution at Xenia, O. They are Cincinnati physicians, and have charge in the order named of the medical, surgical, and eye, nose, and throat divisions.

The Newberry County, S. C., Medical Society was organized early in March. The following officers were elected: *President,* J. K. Gilder of Newberry; *Vice-President,* G. Y. Hunter of Prosperity; *Secretary and Treasurer,* J. G. McMaster of Newberry; *Delegate to the State Association,* W. G. Houseal of Newberry.

Plague in India.—A commission to investigate the best means of combating the plague in India has been organized, and is to leave London immediately. The latest figures show that for the four weeks ending February 28, in the Bombay Presidency there were 13,475 deaths, and that for the four weeks ending March 11 in the rest of India there were 122,550 deaths. The total number of deaths from the plague in the Bombay Presidency from January 1 to February 28 was 28,721, and in the rest of India from January 1 to March 11, 318,178.

"Radium" Doctors Sentenced.—Dr. Henry H. Kane and his assistant, William H. Hale, having confessed to obtaining $10,000 from a Mount Vernon carpenter by an alleged radium cure in which there was no radium, were sentenced last week to serve four and eight months respectively in the penitentiary. As restitution had been made to the victim, the court showed clemency in imposing the sentence.

Fifteenth International Congress of Medicine.—The fifth number of the *Journal of the Fifteenth International Congress of Medicine* is published. It is dated February 20, and contains interesting news. The number of the papers that are assured in the different sections amounts to 205. The programme of the lectures is also very advanced: Sir Patrick Manson, Prof. Brissaud, Drs. José Esquerdo and P. Aaser, and Prof. Azevedo Sodré have accepted already, and the Committee of the Congress expects the acceptance of other scientists that are invited. The organization of the national committees is nearly complete in the several countries.

Columbus Academy of Medicine.—At a meeting held February 6, committees were appointed to arrange for the coming meeting of the Ohio State Society in May. The president, Dr. F. F. Laurence, and secretary, Dr. Chas. J. Sheppard, will be at the head of the committee of arrangements.

The Duodenal Orifice of Vater's Diverticulum.—In the report of the Practitioners' Society of New York, in the MEDICAL RECORD of March 25, Dr. Kinnicutt was quoted as saying that the duodenal orifice of the diverticulum of Vater was 25 m.m. This, of course, as the context clearly shows, should have read 2.5 m.m.

Mental Science Bills.—At a recent meeting of the Public Health Committee at Albany, a bill introduced to make "mental science" a recognized branch of medical practice was defeated. Through its Legislative Committee the New York State Medical Society appeared in opposition to the measure. A bill just passed by the State Senate of Nebraska to regulate the practice of medicine makes it unlawful for any one to heal or pretend to heal or treat by suggestion mental or physical ills, whether imaginary or real. The bill was introduced early in the session, and Christian Scientists and other oddities made a stubborn fight against it.

Dr. Arthur Cushing, professor of Materia Medica and Therapeutics at the University of Michigan, has resigned his chair to take a similar one in the University of London, England.

Hospital News.—*Saturday and Sunday Association.*—The treasurer of the Hospital Saturday and Sunday Association has announced that the collection taken in the synagogues and churches on the last Hospital Saturday and Sunday was nearly double the amount realized in the previous year, and that the aggregate from all sources, which then was barely $75,000, is now above $90,000.

Conference on Hospital Finances.—A meeting was held in this city on March 23 to devise means for improving the financial condition of the private hospitals of New York. The meeting was attended by representatives of every large hospital in the city and of many of the smaller institutions. All admitted the gravity of the situation as shown by constantly increasing deficits in some of the hospital reports. Mr. R. Fulton Cutting, who presided, said he believed the needs of the hospitals had not been brought properly before the public. He suggested a uniform system of accounting, so that the hospitals could compare notes of expenses and the formation of a committee to gather information and bring the public to a sense of the situation. Mr. Tucker said that of ten sug-

gestions made by representatives of hospitals whose views had been asked, that of educating the public to give more was the only one really fundamental. He suggested that the cost per capita, which each hospital now has a different way of computing, should be figured out by an independent body and given to the public. The public, he said, had an idea that $5,000 was enough to endow a bed, whereas $20,000 was really needed to-day. Mr. Oakleigh Thorne, treasurer of the Presbyterian Hospital, suggested monthly reports from each hospital. Mr. Isaac Wallach of Mount Sinai Hospital suggested that each hospital have a roll of members, such as Mount Sinai has, each of whom is pledged to give annually from $10 up, and who should have the right to vote for officers and thus have an interest in the hospital. This plan, he said, yielded an annual income of $120,000 to Mount Sinai. Another suggestion made by Mr. Wallach was that the city should subsidize the hospitals in proportion to the amount each hospital contributed to the support of the sick. Dr. John W. Brannan of Bellevue and allied hospitals made a sweeping condemnation of the methods used in hospitals in this city as wasteful, and told of savings in several directions which had been effected in the city hospitals by "stopping leaks" and the consequent bringing down of the per-capita-per-diem cost from $1.24 to $1.16 at Bellevue. Our American system, he said, is all right from the point of view of training physicians and nurses, but all wrong from the point of view of hospital administration, for no sooner do the members of the house staffs become experienced than they leave. The nurses are not paid anything, either, and are shifted about. This is all right from the standpoint of the nurses, but not for the public. The hospital is the only American institution which has not come under the modern methods of bookkeeping for finding out where every cent goes. Dr. Brannan pointed out that the plentiful supplies of bandages and dressings encouraged in hospitals waste unknown in private practice. "Less waste and you'll get more money from the people," he observed in closing. Other representatives were in favor of the hospitals combining to make a demand on the city for a greater allowance for patients, the amount now paid, 60 cents for a medical patient and 80 cents for a surgical case per day, being, it was declared, ridiculously low as compared with the per capita cost of the different hospitals. It was resolved that Mr. Cutting should name a committee of twelve to study existing hospital conditions, consider the suggestions made, and report a practical scheme of improvement at another meeting.

Bellevue's Highest Record.—More patients are in Bellevue now than have been cared for there at one time in the history of the institution. On one day last week there were 1,050 cases in the hospital, the highest number up to that time having been 1,006, on March 14, 1904. Last year 28,925 patients were treated. On one day in February this year 124 patients were admitted, and the general average is ninety a day.

Nurse Dies of Meningitis.—Miss Jennie Blauvelt, a nurse at the Harlem Hospital, died on Saturday of last week of cerebrospinal meningitis. She was one of a number of volunteers who were called for to take care of the many children suffering with the disease, recently admitted to the institution.

Harlem Hospital Annex.—Plans have been filed for the erection of a three-story ambulance station for the new Harlem Hospital to be built in One Hundred and Thirty-seventh Street, east of Lenox Avenue, and for a power station to be erected on an adjoining lot.

The Mount Sinai Hospital has bought a plot of nearly eight lots on the south side of One Hundredth Street, directly opposite the hospital buildings. The property has not been acquired with any view of adding immediately to the hospital's buildings, but the trustees have thought it advisable to secure the lots and hold them in reserve against the future needs of the institution.

Brokaw Hospital, Bloomington, Ill.—This hospital, which bears the name of Brokaw, recently received $175,000 by the terms of the will of Abram Brokaw of that city.

New Manhattan Eye, Ear, and Throat Hospital.—Ground for the new Manhattan Eye, Ear, and Throat Hospital was broken on Thursday of last week with appropriate exercises. The new building will be on the south side of East Sixty-fourth Street, between Second and Third Avenues. The Hospital is now at Park Avenue and Forty-first Street. Mrs. C. R. Agnew, widow of Dr. Cornelius R. Agnew, removed the first shovelful of earth. John Sinclair, president of the hospital, presided. Dr. Andrew H. Smith reviewed the history of the institution, and the Rev. Dr. Stephenson of the Fifth Avenue Presbyterian Church offered prayer. There will be sixty rooms for private patients, and accommodations for 150 ward patients.

Bequests to Chicago Hospitals.—Each of the following hospitals has been bequeathed $2,000 by the will of the late John Murphy: Alexian Brothers', St. Luke's, Mercy, and Chicago Presbyterian.

National Fraternal Sanatorium for Consumptives.—A committee representing eight millions of fraternalists of the country recently spent three weeks visiting different cities in the South and Southwest with a view of selecting a suitable location for the National Fraternal Sanatorium for Consumptives. Mr. William R. Edison, the chairman, stated that offers of land had been made by various cities and individuals, ranging from 4,000 to 100,000 acres, all of it under cultivation, and to be donated free from obligations. As soon as the site is selected the building used at the World's Fair as the Temple of Fraternity will be transported to the grounds and used as an administration building in the camp settlement.

Obituary Notes.—Dr. John Oscroft Tansley of this city died on March 26, at the age of sixty years. He was born in Basford, a suburb of Nottingham, England, in 1844. His father came to this country in 1847, settling in Enfield, Conn. His education was received in the village of Scittico, near Enfield, at Williston Seminary, Easthampton, Mass., and elsewhere, and he began the study of medicine under Dr. E. L. Draper of Holyoke, Mass. He graduated from the College of Physicians and Surgeons in this city in 1877, and soon afterward received an appointment as assistant surgeon in the Manhattan Eye and Ear Hospital in this city.

Dr. Alexander F. H. Gale of this city died at sea, while on the way to Bermuda, on March 17. He was born thirty-seven years ago and was graduated from the College of Physicians and Surgeons in this city in 1887. He had suffered from a severe attack of influenza shortly before sailing, and had taken the trip in search of health and rest.

Dr. Amos H. Brundage died of apoplexy at his home in Brooklyn on March 19, in his seventy-seventh year. He was born at Benton, Pa., and was graduated in 1855 from the Medical College of the New York University. He served as a surgeon under General Sheridan in the civil war. He was a member of the Brooklyn Medical Society, and one of the founders of the New York State Medical Association.

Dr. JOHN P. LOMBARD died March 20 at his home in Boston from heart failure. He was born at Medford, Nova Scotia, February 14, 1861, and was graduated from New York University Medical School in 1887.

Dr. HORACE WARDNER of La Porte, Ind., died March 18. He was a graduate of the Rush Medical College, Chicago, in the class of 1856. During the civil war he was assistant medical director on the staff of Gen. Grant.

Dr. E. JULIUS BOEBER of Kansas City, Mo., formerly assistant city physician there, died at Guadalajara, Mexico, on March 15, of tuberculosis, at the age of thirty-four years. He was a graduate of the Kansas City Medical College in the class of 1897.

Dr. RUSSELL MURDOCH of Baltimore died March 18, at the Johns Hopkins Hospital, of apoplexy. He was born in Baltimore in 1839, but spent much of his early life in Scotland. He was educated at Edinburgh University and returned to this country and took his medical degree at the University of Virginia in 1861. After graduation he became a surgeon in the engineer corps of the Confederate Army. He was one of the founders of the Baltimore Eye, Ear and Throat Charity Hospital, on West Franklin street, and was one of the attending physicians there from 1882 until his death.

Dr. WILLIAM MEYER of Milwaukee died March 15, at the age of forty-nine years. He was born in Milwaukee and was graduated from the Rush Medical College, Chicago, in the class of 1879.

Dr. MOSES RICHARDSON of Norcross, Ga., died March 15, at the age of seventy-five years. He was born in Newton County, Ga., and was graduated from the Jefferson Medical College, Philadelphia, in the class of 1856. He served as surgeon in the Confederate Army during the civil war.

Dr. SAMUEL B. HOPPIN died at Philadelphia on March 21, at the age of eighty-seven years. He was graduated from Jefferson Medical College in the class of 1852. At the outbreak of the civil war he became a surgeon in the United States Navy, retiring at the close of the war. Subsequently he became registration physician in the Prothonotary's office, and he continued in this position until his death.

Dr. H. A. B. KLIPPEL died at Quarantine Hospital, near St. Louis, March 17. Dr. Klippel was a graduate of the Missouri Medical College, 1899, and also a graduate in pharmacy, 1895. He was medical examiner for a number of fraternal and benevolent organizations and an alumnus of the St. Louis College of Pharmacy and the Missouri Medical College. He volunteered to attend to smallpox cases at the quarantine station and contracted the disease while in the performance of his duty. He was born in St. Louis in 1876.

Dr. GEO. M. ARMSTRONG of St. Louis died in that city March 22, from the effects of an overdose of morphine. Dr. Armstrong graduated from the Jefferson Medical College of Philadelphia in 1871 and resided in St. Louis since his graduation. He was fifty-eight years of age when he died, a member of the A. O. U. W. and a well-known Mason. He was a collector of curios, of which he had a large assortment gathered from all parts of the world.

Dr. FREDERICK DANNE died at his home in this city, on March 27, at the age of sixty-nine years. He was born in New York City, February 12, 1837, and was educated at Brown University and in Germany. On returning to this country he studied at the New York University Medical School, and was graduated there in the class of 1863. Dr. Danne was a member of the Medical Society of the County of New York and of many clubs and other social organizations.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE ADJOURNED DISCUSSION ON APPENDIX CASES—PROPOSED ACADEMY—CRITICAL OTOLOGISTS—LINCOLN EPIDEMIC—ITEMS.

LONDON, March 10, 1905.

THE adjourned debate at the Medico-Chirurgical Society on the later history of cases operated on for appendicitis was resumed on Tuesday, when the president, Sir D. Powell, said he had met with pulmonary embolism more frequently than after other operations, and though statistics did not show this, probably many of the cases of pleurisy were really due to pulmonary infection. As a preventive of this complication it would be advisable in chronic cases to prepare the patient by rest in bed for a few days on a simple diet, and to give small doses of calomel as an intestinal disinfectant.

Dr. H. P. Hawkins remarked that in spite of earlier operations, the mortality had not fallen, and in some cases had increased, in the last decade. The rise had been as much as 3 per cent. All would allow that the disease was on the increase, and he thought the higher mortality was due to an increase in the number of severe cases with general peritonitis and abscess. Mucous colitis might simulate appendicitis, so might neurasthenia and secondary hypochondriasis. In such cases operation would not relieve.

Sir Wm. Bennett said hospital statistics were less favorable than reports of private practice. He considered it was not advisable to remove the appendix in abscess cases. He had never regretted leaving it, but more than once had regretted attempting to remove it. In simple cases a stump should not be left, as it might cause trouble. A ureteral calculus had given rise to symptoms. *X*-rays should be used in any doubtful case. No prolonged pain in the scar would occur if no ligature was applied through the undivided peritoneum.

Mr. C. B. Lockwood said the future of the patient depended on the disease of the appendix when it was removed. Some were tuberculous, others cancerous, others actinomycotic, and microscopical examination, and, if possible, bacteriological, should supplement the clinical evidence. If appendices were systematically examined after removal, he thought 1 in 250 would be found cancerous. In his 200 cases four were tuberculous. The commonest disease was ulceration of the mucosa with penetration of bacteria. It might be associated with septic, or mucopurulent, or fecal contents. In the last case, concretions were frequent. In operating for other diseases, if the appendix were found to contain a concretion, it was better to excise it. Recurrence of symptoms might be due to dilatation of the cecum by retained feces, and must be treated by enemata.

Mr. W. H. Battle mentioned five cases of recurrent symptoms after the evacuation of abscess. The appendix subsequently removed showed marked disease. A sinus followed in six other cases. He advocated early evacuation of an abscess, and secondary removal of the appendix, in most cases. The escape of a concretion was no guarantee against recurrence.

Mr. Turner operated as early as possible on acute cases, unless they were obviously convalescing. Mortality and complications would both be reduced by earlier operations.

Mr. Waterhouse also advocated early operations. In nineteen cases operated on within twenty-four hours there was not a death, although in three of them perforation had taken place. He protested against removing the appendix when evacuating an abscess.

Mr. Mummery had collected statistics of 3,225 operations, and found the percentage of complications 27, but, omitting the deaths, 18. He believed these percentages too low if every complication could be tabulated.

The discussion was then adjourned.

Why should not London have an Academy of Medicine? This question has often been discussed, and on more than one occasion a project for the establishment of such an institution has come near to its fulfillment. But on each occasion, either from mutual jealousies, diverging interests, or other difficulties, the proposal has been abandoned or passed over to "a more convenient season."

The question has again been started—almost as if it were a new one—and to some of our younger friends it really is so. We have numerous societies devoted to medicine in all its branches, and the project has usually been for a more or less complete amalgamation of them. The Royal Medico-Chirurgical Society is acknowledged to be the principal one, and again and again the proposal has been to unite with it. The last proposition comes from its President, Sir R. Douglas Powell, and was made in his address at the annual meeting, held on the 1st inst. The idea was

supported by Sir T. Smith, Mr. Timothy Holmes, Dr. Goodsall, and Dr. Allchin. The President, who must have been aware that his proposal was not a new one, thought the present a suitable time to make it, and offered some practical suggestions for a kind of federation. Certainly something of the kind seems desirable, though when one looks at the number of distinct organizations which exist it is easy to realize how divergent interests have hitherto rendered union impracticable.

The subscription to the Medico-Chi. is the highest of all and often deters younger members from becoming candidates. On the other hand, the library is very valuable and would certainly have to be provided for in any reasonable scheme. Unless federation largely increased the fellowship, it would be a disastrous failure. Most other questions would admit of easier solution. But Ireland has carried amalgamation in a similar case, and has for some years had her Academy of Medicine, with sections for the several branches. The annual meeting passed a resolution requesting the council of the society, with as little delay as possible, to invite the leading medical societies of London to arrange for a joint meeting to consider the advisability of amalgamating, and to take the necessary preliminary steps for the purpose. I should add the important news from the report, that the society's finances are now flourishing—in fact, more so than ever. The centenary of the society will be celebrated in May. The arrangements for this one are pushing well forward.

The proceedings of our societies are, as a rule, so sedate and unexciting—some call them "dry"—that a little sharp criticism comes almost as a surprise and relieves the tendency to somnolency of post-prandial discussion. A paper at the Otological Society deserves a word, if only on account of the lively remarks it elicited. It was on restoration of hearing after removal of drum and ossicles by a modification of the radical mastoid operation for suppurative ear disease. The paper was published in the *Lancet* last December, a fact which naturally provoked remark that discussion at a society, if invited, should come before publication elsewhere. The author, Mr. Ch. Heath, was complimented on his results by some members, and severely criticised, as I have said, by others. Prof. Urban Pritchard expressed a fear that Mr. Heath had operated on many cases which other otologists would not consider required such a proceeding. Mr. Yearsley ridiculed the statement that in a large percentage of cases the whole of the disease was confined to the limits stated. Dr. Milligan held that no modification of Stacke's operation was needed, and that the number of cases reported was almost staggering, for not more than 4 per cent. in his aural clinic required the operation. Mr. Ballance held that only the slightest and most limited disease could be removed or even exposed by the operation. Mr. F. Spicer said by adopting Mr. Heath's methods he had reduced by one-half the time patients were under treatment. Dr. MacNaughton-Jones could not think so large a proportion of cases required to be operated on. Mr. Cheatle moved that the meeting proceed to the next business, but though seconded, the proposal was not adopted. Dr. Pegler regretted the course the discussion had taken, and the president threw some oil on the troubled waters, suggesting that Mr. Heath was an earnest man, anxious to do right, and that his enthusiasm might have suffered less criticism if his notes of cases had been more precise. Mr. Heath replied on various points, and said many patients, after operation on one ear, were so gratified with the result as to beg him to operate on the other.

The typhoid epidemic at Lincoln is abating, but by no means over. About 800 persons have been attacked. There were 769 notifications with 77 deaths up to March 3. The new cases reported were 37 as against 63, 116, 174, and 284 in the four preceding weeks. The report of the inspectors sent by the Government Board expressed the belief that on February 28 the water sent into consumption and that in the reservoir had become fit for consumption. Nevertheless until a better supply has been obtained they recommend the treatment with hypochlorite of sodium to be continued under constant supervision and frequent analyses. Further they do not feel justified in saying that the additional precaution of boiling may be discontinued.

The Directorship of Cancer Research in Liverpool has been accepted by Prof. J. E. S. Moore, of the Royal College of Science, who was associated with Messrs. Farmer and Walker in their investigations.

On Tuesday, the King advanced Sir F. Treves to the Grand Cross of the Victorian Order, of which he was previously Knight Commander.

Deputy Surgeon-General W. Perry, late of the Royal Artillery, who died at Hereford in his eighties, had served through the Crimean War, was at the battles of Alma and Inkerman, and held the medals for them as well as for Sebastopol. He also was awarded the Sardinian and Turkish medals, and the order of Medjivich. He retired in 1879.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

A SEWER SYSTEM FOR MANILA—PROBLEMS INVOLVED—DISAPPEARANCE OF THE PLAGUE IN CEBU—A MEDICAL MOVEMENT—DR. T. R. MARSHALL—DR. W. R. [illegible].

MANILA, P. I., January 18, 1905.

ONE of the greatest benefits which the Philippines will derive from the "Cooper bill," which recently passed Congress, is probably that sufficient funds will become available for the purpose of installing a sewer system in the city of Manila. It will, perhaps, be remembered that the greater portion of Manila is entirely unprovided with sewers and that the many canals or esteros which pass through the city not only serve the purpose of providing cheap water transportation, but also serve the purpose of drainage and as a means to carry off sewage. In many portions of the city the flushing of these canals was very difficult, with the result that the water became stagnant, and the odors which arose therefrom were almost unbearable. This latter condition has, however, been very much improved during the past year by dredging the canals and thus causing a better tide flushing. The services of an expert engineer from Boston have been obtained in order that he might give an authoritative opinion as to the best plan to adopt. The problem of successfully accomplishing this object is indeed a difficult one. The entire city is only a few feet above high tide. The tides are extremely irregular. Some days there are three and upon others there are only two. There is only one tide per day which reaches any dimensions worth speaking of and that amounts to about three feet. The others are only a matter of a few inches. Almost anywhere in the city a hole dug to the depth of a few feet will contain water at its bottom, due to seepage. From the foregoing it will be seen that the ordinary gravity sewerage system is entirely out of question. The final disposal of the sewage was another difficult problem. The establishment of a sewage farm was suggested, but when it was considered that this is a tropical city, that dysentry is constantly present, and that cholera is not unlikely, it was concluded that disposal in that manner was not safe. Experiments made in Boston showed that no trace could be found in the sea of sewage from a sewer that emptied three-quarters of a mile away. With this fact in view it was decided to carry the mouth of the sewer about a mile into Manila Bay. It is proposed to erect a large receiving receptacle in the Tondo district near the water's edge. The sewage will flow into this tank by gravity and will then be pumped into the bay. A number of smaller or sub-stations will be erected at different points throughout the city at which pumps will also be installed. The plans for the new system have been completed. The Municipal Board is at present engaged in considering the specifications. The work is to be advertised in the principal cities of the United States and bids solicited. It is estimated by those having the matter in charge that the actual construction will be commenced in about six months. With the sewer system once in working order the Manila health authorities will be in a far superior position to make Manila a thoroughly sanitary city.

The city of Cebu, after enjoying an entire absence from plague for nearly a year, again had a death from plague on January 14, 1905. It appears that for some weeks previous a great number of dead rats were found in the immediate vicinity of where the victim lived. No particular attention was paid to this fact, because it was presumed that they had been poisoned. Soon after the case was discovered the mortality among rats ceased, and for that reason it was not possible to verify the suspicion that the deaths among the rats was due to plague. At the post-mortem which was made in the case it was found that there was a large femoral bubo, the lymph glands containing numerous hemorrhages. Smears made from the latter and examined microscopically showed characteristic plague bacilli. The victim had not been out of the city for a number of weeks, and it may therefore be reasonably assumed that the infection was contracted in Cebu.

Another great nuisance which, owing to its obnoxious smells, has been much blamed by the laity as a cause of disease is the moat, which in a short time will pass into history. This moat extends entirely around the walls of the walled city. Some sewers empties into it and it is covered over with a growth of rank weeds. The stench from it is at times unbearable. Arrangements have been made with the contractors who are engaged in dredging the harbor to pump the sand from the bottom of the bay into the moat, thus eliminating it entirely.

Dr. Thomas R. Marshall, the Chief Health Inspector of the Philippine Islands, has left for Isabella and other northern provinces for the purpose of inspecting the

method of vaccination that has been pursued in those districts during the past few months.

Dr. Walter Remsen Brinckerhoff, of the Harvard Smallpox Commission, who has been engaged in studying smallpox in Manila during the past year, has completed his labors and has returned to the United States.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 23, 1905.

Appendicitis.—This issue of the Journal is given over to the consideration of various aspects of the appendicitis. C. A. Porter asks "Can we wait for localization when the general peritoneal cavity is involved?" Special attention is given to the views of Ochsner of Chicago, who in cases in which it appears that infection is spreading or has spread to neighboring parts, advises a delay in operation and follows this plan of treatment: From the start absolutely nothing is given by mouth—no water, no cathartics. The stomach is washed out, thereby overcoming the nausea, vomiting and distention, and the patient is put in an exaggerated Fowler posture. Water is freely supplied by rectum or saline infusions under the skin, and small nutrient enemata are given every four hours. Large enemata are not given from fear of rupturing adhesions. Hot or cold applications to the abdomen are made and the treatment is kept up until the diffuse process has become localized or the patient has died. Porter's conclusions may be condensed as follows: Purgatives should never be given before operation. The Ochsner plan is the best one to follow from the start, and when an operation is refused. It is also the best to employ in almost all cases after operation. This conclusion is justified by Ochsner's own statistics. His rules must be rigidly followed and not misapplied. His plan should be advised in most cases of spreading or diffuse peritonitis when a reasonably good surgeon cannot be obtained. Irrigation of the general peritoneal cavity a major operation not to be undertaken unless the conditions are such that it can be thoroughly performed. After irrigation the danger of increased absorption is best prevented by a tube or cigarette drain to the bottom of the pelvis, or, in women, vaginal drainage with exaggerated Fowler for from twenty-four to thirty-six hours. Porter thinks that natural peritoneal resistance is a most, if not *the* most important factor in overcoming infection, provided the abscess and the pelvis are drained or the appendix removed in the shortest possible time, with the least amount of trauma and without spreading infection. The question whether the operation should stop at this point or be followed by a general saline irrigation appears to be one of secondary importance; it may be that the one advantage of irrigation is neutralized by its disadvantages.

M. H. Richardson believes that the earlier a case of appendicitis is operated on, the surer the patient is to recover. The mortality of abdominal surgery to-day is that of abdominal emergencies and of delay. He operates as early as possible after the first symptom. Deaths are caused as a rule by the failure to remove the nidus of infection before it has done irreparable damage. Of course, the existence of a pneumonia, severe bronchitis, or serious cardiac difficulty, may furnish exception to the above rule. Improvement in technique has reduced to a minimum the danger of breaking up adhesions with a consequent spread of infection. Richardson does not believe that we can safely wait for localization in cases in which the general peritoneal cavity is involved. During the past year he has had 112 operations with only three deaths.

R. H. Fitz discusses the question from the medical point of view, and expresses his opinion as to the matter of immediate operation *versus* delay in the following words: The physician is justified in delay until the conditions call for an immediate operation. These may be present at his first or may not appear till a later period. If after twenty-four hours there is no improvement, and especially if the fever increases, an immediate operation is preferable to further delay. The surgeon may be expected to perform an immediate operation upon his arrival under the above circumstances.

New York Medical Journal, March 25, 1905.

Osteoarthritis of the Spine.—The history of a case is reported by H. F. Stoll, his patient being a baker, aged thirty-eight years, who ten months before admission to hospital, noted a "heavy" feeling in the small of the back. Later came cramps in thighs and legs. At first the pains were felt on waking and would wear off as the patient "limbered up," but later became constant. Then appeared a swelling of the right hip, and the pains grew so severe that he was frequently obliged to rest while on the street. On admission to hospital it was noted that the right hip was so held that there appeared to be considerable fullness extending from the crest of the ileum to the right trochanter major. The gluteal folds were equal. There was a double scoliosis, the smaller one with its concavity to the right being in the upper dorsal region, and the large one in the lower dorsal and lumbar regions. Flexion of the vertebral column was much limited, especially in the lower half of the dorsal and lumbar regions. Flexion to the left was normal, but much limited to the right. Extension was also somewhat limited. When in dorsal decubitus the position of ease was with the right leg flexed on the thigh, and the thigh on the pelvis, the whole extremity being rotated outward. There was no shortening of the legs and no atrophy. There was no limitation of movement at the hip joint, nor was there any tenderness over the sciatic nerve. The prominence observed over the right hip when erect was not present in ventral decubitus. The knee jerks were equal and exaggerated. There was no ankle clonus. The heart, lungs, and abdomen were negative. A plaster jacket was applied and there was a marked relief of the pains. The scoliosis disappeared, and he was able to walk without difficulty. Discontinuance of the jacket (which was renewed from time to time), led to a reappearance of symptoms which went away as soon as its use was resumed.

Indications for Treatment of Gastric Hemorrhage.—F. Gregory Connell discusses the subject of gastric hemorrhage as related to ulcer, and says that in acute symptomatic hematemesis, prophylaxis is the only rational treatment; that is in chronic ulcer radical cure should be instituted *before* hemorrhage comes on. In acute non-symptomatic cases, indications for treatment are not so definite. It may be difficult even at autopsy, to determine its cause. After single acute hemorrhages of either the symptomatic or non-symptomatic variety, medical treatment is usually advocated and instituted. It must be remembered, however, that the amount of blood vomited is no indication of the amount of hemorrhage, as considerable may pass into the bowels. The majority of acute single hemorrhages are capillary oozings, and many cease as spontaneously as they begin; hence palliative treatment is indicated. After acute multiple hemorrhages the question of surgical intervention comes in. Drawbacks to operations at this time are (1) that the patient is in poor condition to go through a major operation and (2) that cases do recover after repeated profuse attacks of hematemesis under palliative measures. The author sums up by saying that it may be stated as a general proposition that after a single hemorrhage, palliative treatment is indicated; after three or more hemorrhages, surgery should be resorted to. As to the proper line of treatment to be instituted after a second acute hematemesis, there can be found a great diversity of views. In general, the greater number of operators have, up to the present time, advocated a waiting policy, and a building up medical treatment, in the hope that the hemorrhage would not be repeated.

Medical News, March 25, 1905.

Roof Gardens on City Private Houses.—Some suggestions (with illustrations) are made by W. P. Northrup in regard to the utilization of the roofs of ordinary city houses. Children often droop in the city because they cannot really live in the open air, as do country children. In town they may go to the Park, but they must be dressed for it, the nurse must dress herself, and by the time all are ready to go out, the children may be too warm in their wraps. They are subjected in their outing to many street dangers, rarely remain out more than two hours, and often return home cross, tired, and jaded. Northrup describes the results obtained in the case of one family, the proper methods for getting the roofs ready, and various amusements which children may properly be entered into under the conditions noted. The total expense of roof preparation in this special instance was about one hundred and fifty dollars. Wise nurses are required, and some moral courage on the part of the parents.

The Purpose of Eye-Glasses.—The conclusions of E. M. Alger are as follows: (1) Improvement of sight is only one function of glasses. (2) Relief of eyestrain is fully as important. (3) Eyestrain is often responsible for headache and other reflex nerve phenomena. (4) One may have perfect vision and still be subject to eyestrain. (5) Small errors of refraction often cause more strain than large ones, since there is a more constant effort to overcome them. (6) Strain can generally be relieved by properly fitted glasses. (7) Glasses which give the best vision may simply increase the strain, and therefore the patient cannot safely select his own glasses; as, furthermore, he will not buy of an optician glasses which do not improve vision, he very seldom gets the correct glass and, therefore, fails of relief.

American Medicine, March 25, 1905.

Is the Common House Fly a Factor in the Spread of Tuberculosis?—J. O. Cobb draws attention to the fact that several observers have demonstrated that the fly may carry tubercle bacilli on its feet and in its stomach. This being

true it must be a dangerous source of infection among the poor where the food is left exposed to contamination by these insects. Data collected from all parts of the world, prove that wherever people have tuberculosis they also have the fly as a pest. He insists that special effort should be directed to the destruction of all sputum, thus removing the sources of infection.

Extensive Carcinoma of Tongue and Neck, Presenting Points of Special Interest.—William Seaman Bainbridge reports the case of a man of 49, an inveterate smoker for 20 years, who was first aware of his trouble in May, 1903, when a small pimple appeared half-way back on the [illegible] of the left half of the tongue. This would disappear under local applications, with discontinuance of smoking, only to return when smoking was resumed. The pimple finally persisted, growing rapidly, and in December, 1903, the author took charge of the case. The patient was somewhat cachectic and had lost considerable flesh and strength. The anterior third of the tongue, except the tip, was involved by a hard, crater-like ulcer. No glands were palpable at this time. Microscopical examination confirmed the diagnosis of vascular epithelioma. On March 11, 1904, the patient was operated upon. The first incision extended from the tip of the left mastoid process to that of the right, and below as far as the thyroid cartilage. The second incision extended along the anterior border of the left sternocleidomastoid muscle to within an inch of the clavicle. The two lingual arteries were tied in situ, the submaxillary and the sublingual glands on either side removed, and the salivary ducts extirpated clear into the mouth. Many cancerous glands were removed from the region of the tonsil on either side. The lymphatic glands with their ves[illegible] were removed en masse as far as possible, and with them the connective tissue and fascia of all the contiguous muscles. The wound was completely closed except for a small drain at the lower part. The mouth was next forced open and the growth on the tongue cut down with Paquelin cautery, Whitehead's shellac being applied as a coating to the cauterized surface. The wound healed by primary union. On March 28 the left corner of the mouth was incised to the edge of the masseter muscle, the mouth forced open, the tongue drawn out, and an elliptic incision made on the floor of the mouth, encircling the tongue, this organ being completely removed. A bridge of tissue was made across the fauces in front of the epiglottis by a small flap of mucous membrane dissected away from the right glossoepiglottic fold. The wound in the floor of the mouth was partially closed by chromicized catgut, the [illegible] to the cheek closed in the usual way and shellac applied over each. Within a few hours the patient could swallow fluids, and on April 21 was discharged cured. Since that time he has steadily gained in flesh, is apparently perfectly well, is able to masticate even solid food, to taste, to talk intelligently, and even to sing.

Delirium and Hallucinations of Digitalis.—H. O. Hall calls attention to the fact that digitalis even in moderate doses, frequently causes hallucinations and delirium, these symptoms as a rule being mistakenly attributed to the disease. He urges physicians who are in the habit of prescribing digitalis to give closer attention to the symptoms following its administration and that they make known the results of their observations with a view of definitely ascertaining if his opinion is well founded. Hall suggests that in all cases of heart affections, in which delirium is present, it would be well, before pronouncing it a symptom of the disease, first to ascertain by elimination, whether the delirium of hallucinations, and even very nervous symptoms, were not directly due to medication—in other words, to the toxic effect of digitalis or other powerful heart stimulants.

The Journal of the American Medical Association, March 25, 1905

Tuberculosis.—Norman Bridge insists on the importance of reinforcing the nutritive forces of the body as the chief agency in the cure of tuberculosis. The fear of draughts is a popular error; another is overfeeding and the recommendation of alcoholics. Still another is the indiscriminate recommendation of exercise, as if muscular development could help to resist the disease. He also opposes deep-breathing exercises. What we need is a safe and efficient method of putting the sick lung at rest in all unilateral cases. Another error is the use of ergot in hemorrhage, tending to increase the blood pressure, and the administration of salt solution in exsanguined cases, thus again distending the vessels and opening up their lesions. The patient is most likely to survive a large lung hemorrhage when the blood pressure of the parts is lessened to the utmost for the time. Still other errors are the recommendation of indiscriminate eating taxing the digestive powers, errors of clothing, the injudicious recommendation of change of climate. In Illinois, patients, by proper management, can be given 85 per cent. of the benefits of the very best climates. With the modern treatment of the disease properly carried out, in almost any climate its mortality can be reduced another 10 per cent., and this no [illegible] will be effected.

Treatment of Idiopathic Epilepsy.—D. R. Brower says that spontaneous cure of this disease is possible, and mentions one of several cases in his observation. He calls attention to the necessity of more care as to the prevention of the trouble, especially in infants suffering from convulsions. The proper treatment and [illegible] in these cases may prevent the later development of the disease. The treatment of the individual convulsions is also important, and the aura may afford a warning that enables the patient to abort the attack. He advises the carrying by epileptics of nitrite of amyl pearls for this purpose. Other methods may also be effective in special cases. In epilepsy there is an autointoxication, usually of gastrointestinal origin, and the diet should be carefully regulated. These patients are usually very hearty eaters, and it is advisable to restrict the diet in quantity, to regulate periods of eating and to insure thorough mastication and digestion. Intestinal elimination must also be attended to, and for intestinal antisepsis he finds salol combined with phytolacca often very useful. For combating the nervous irritability the bromides are most useful, and he prefers the sodium salt. Their overuse, however, is dangerous, and Brower refers much of the existing epileptic insanity to this cause. The dose should seldom exceed sixty grains daily, in plenty of water after eating, and he sometimes adds fluid extract of *Solanum carolinense* in one-half to two drachm doses to the bromide mixture. Strychnine is also a valuable remedy for meeting the circulatory and vasomotor defect, and he specially recommends fluid extract of *Adonis vernalis*. Cerebral sclerosis calls for alteratives. In conclusion he insist on the importance of allowing plenty of time, at least five years after disappearance of symptoms, before claiming a cure of epilepsy.

Splenomedullary Leukemia.—Everett J. Brown and Cecil M. Jack report the final outcome, with autopsy findings, of a case of this disease apparently cured by *x*-ray treatment, described in the *Journal* of March 26, 1904. In the fall of 1904 the patient began to become weaker, the spleen enlarged again and he finally succumbed with typhoid-like symptoms just sixteen months after first coming under observation. The macroscopical examination showed a somewhat enlarged spleen, some kidney lesions, and no special gastrointestinal abnormalities. The pathological examination showed a marked fibrosis of the spleen with a general picture of splenic anemia, no evidence of leukemia in the intestines or lungs, extensive deposits of lime salts in the kidneys, involving especially the convoluted tubules, and the lymph glands showed a lymphoid hyperplasia, resembling that of lymphatic leukemia, these being the only pathological findings suggestive of leukemic disease. A. S. Warthin, who made the pathological examination, remarks that the only conclusion justified by the findings would seem to be that the *x*-ray treatment had resolved the leukemic condition into an aleukemic state, but that the essential disease process, as shown by the lymph glands, was still active. The leucocytes had been removed from the general circulation and from the areas of infiltration, and the splenic changes seemed to be secondary. The remarkable condition in the kidneys offers room for some speculation as to the source of a toxin such as might result from very extensive destruction of leucocytes. No specimen of bone marrow was secured.

Urine Examination.—R. C. Cabot states that incited by a statement of Councilman that the chemical and microscopical examination of the urine failed to give certain information of the character of the renal lesions, as well as by discrepancies coming under his own observation, he has compared critically the records and post-mortem findings in the cases that have come to autopsy in the Massachusetts General Hospital since 1893. Although the number of cases is not large, he thinks they warrant the following conclusions: (1) Many cases of acute glomerular nephritis occur that are unrecognized by any known methods of examination. (2) The diagnosis is at fault in some cases of subacute and chronic glomerular nephritis, but in the great majority of cases the condition of the urine, taken in connection with other symptoms, foretold the autopsy findings. (3) In chronic interstitial nephritis the diagnostic resources appear to be neither so sufficient as in the chronic glomerular form, nor so inadequate as in the acute glomerular nephritis. In about a third of the cases, the diagnosis was correctly made before death. (4) Among other conditions mistaken for nephritis by too much reliance on the urinary findings, are senile and arteriosclerotic condition, mistaken for chronic nephritis, while in conditions involving passive congestion or acute kidney degenerations, the urine occasionally simulates that of acute nephritis. Even when no lesions are found at autopsy, the urine is sometimes highly albuminous and full of casts. (5) In ordinary urinary examinations the common errors are: (*a*) The attempts to estimate

urea without accurate knowledge of the patient's metabolism. (*b*) Stating that renal cells are present when all that is seen are small mononuclear cells, perhaps from the kidney tubules, perhaps not. (6) Cryoscopy and other attempts to test the renal permeability more directly are not yet capable of supplementing in clinical work the older methods of examination. Cabot holds that the vast majority of estimations of urinary solids, including urea, are a waste of time, since they are not and cannot be made part of a general metabolism experiment, and that the attempt to estimate the anatomic condition of the kidney by measuring albumin and by searching for casts is fallacious. The most reliable data are the twenty-four-hour quantity, the specific gravity and the color.

The Lancet, March 11, 1905.

A Method of Extension of the "Gridiron" Operation for Appendicitis without Dividing the Muscular Fibers.—The method described by M. P. Holt, consists in the separation by a few touches of the knife of the tendon of the external oblique muscles from that of the internal oblique, where these begin to blend together for the formation of the sheath of the rectus, to well beyond the outer edge of the rectus and their retracted muscles, the incised opening of the external oblique and transversalis muscle is then carried on through their tendons well on to the rectus sheath for an inch or so; the remaining part of the anterior sheath of the rectus is then divided upwards, or downwards, whichever be desired, as far is is necessary; the rectus is then displaced inwards and the posterior sheath is similarly divided in a vertical direction, in a line a full inch nearer the middle line than the site of the outer border of the muscle. The triangular flap thus obtained is displaced outwards and downwards (or outwards and upwards, as the case may be). The incision in the peritoneum is easily extended to any desired point in the line of original incision and very free access is obtained. This method takes but a few minutes but its chief advantages are only obvious when the layers are severally united by sutures. When the posterior sheath of the rectus has been sutured, the rectus muscle secured by a few points in its original bed, and the anterior sheath similarly united; the internal oblique and the transversalis muscles will be found accurately joining together in the line in which they were split; the external oblique, of course, comes together without the least difficulty. In this way there has been no division of muscle fibers and the nerve and blood-supplies to the rectus are practically untouched.

The Diagnosis and Treatment of Hypertrophy of the Pylorus in Infants.—G. F. Still finds that this condition of the pylorus is more common in male children. The condition is primarily due to pyloric spasm. Symptoms come on, in his experience, from the fourth to the seventh week after birth, practically always before the third month, and unless vigorous measures be adopted, the children rarely survive the fourth month. Nevertheless the lesion may be practically a congenital one. Vomiting is not proof positive of its existence. It is forcible in character, occurs in spite of most careful breast feeding, is persistent in spite of the various measures which usually control this symptom and its amount is so large as to show that one vomitus represents more than one feeding—perhaps the accumulation of several feedings in the dilated stomach. Association of constipation with this persistent vomiting is of some importance in diagnosis. The child wastes rapidly. The two characteristic signs are visible penstalsis of the stomach (examination should be made immediately after feeding), and palpable thickening of the pylorus. Treatment is considered under the headings of dietary, nasal feeding, stomach washing and operative measures. These are all elaborated by the author. Under the last-named heading the mentions forcible dilatation of the pylorus, pyloroplasty and gastro-enterostomy. Seventeen of nine of his twenty cases were treated by dilatation and recovered. Operation has risks apart from those connected with shock and with the operation itself. There is a tendency to looseness of the bowels after it and also a difficulty of nutrition, which in some of my cases seemed to make death from marasmus almost inevitable for some weeks after the operation, although they ultimately recovered; an important point this, which increases the need for careful consideration before embarking on operative measures, and which increases also the importance of previous stomach washing if thereby even a few ounces of weight can be gained. Stomach washing should be given a thorough trial before surgical measures are resorted to.

Acute Ascending Paralysis in Cases of Chronic Cystitis.—Three cases have come under the observation of T. J. Walker, who gives their clinical histories. All were characterized by a sudden invasion, rapid course and fatal termination. The exact cause of this terminal complication is unknown. Various theories are passed in review. The consensus of opinion inclines to Leyden's view of a urinary paraplegia, though there is a possibility of the condition being a reflex paralysis. No bacteriological investigations have been made. Landry's paralysis is generally regarded as an intoxication of the nervous centers due to infection by specific microbes and that urinary paraplegia is the result of the spreading from the urinary organs to the lumbar portion of the cord of a specific inflammation, and the author thinks there are grounds to justify a probable explanation of the pathology of the cases to which he directs attention. In every infection three factors are necessary: (1) The presence of microbes having active infective powers; (2) a medium in which these microbes, when conveyed to it, can develop; and (3) the resistant power of the tissues must be weakened. He suggests as a provisional view that in his cases these factors existed. First, the specific microbes were to be found in the urinary organs, probably in the bladder; secondly, at a certain stage of the disease they were conveyed along the same course, almost certainly the nerves, by which inflammation spreads from the urinary organs in paraplegia urinaria to the cord, in which medium they developed rapidly, producing a virulent intoxication; and thirdly, the tissues were weakened by the long-standing cystitis.

British Medical Journal, March 11, 1905.

Some Practical Aspects of Conjunctival Bacteriology.—Freeland Fergus declares that there are few conjunctival sacs which appear to outward observation to be normal in which microorganisms are not found. Some of these microorganisms are not pathogenic, such as the bacillus xerosis. The importance of bacteriology in the eye clinic is very great. It is a valuable aid to diagnosis; it is a guide in determining the safety of any operation; and it materially influences views of treatment. By no other method can it be absolutely determined in the early stages whether a given case of inflammation of the conjunctiva is due to the gonococcus, to Morax's diplobacillus, or to Week's bacillus. Disaster can often be prevented by a thorough bacteriological investigation before operation is attempted. The writer refers to several cases in point. He has known in his own experience the streptococcus to cause the loss of three eyes after cataract extractions. He declares that no operation which involves the opening of the ball should be undertaken if bacteriological investigations reveal the presence of staphylococcus aureus, streptococcus, pneumococcus, or any other well-defined pathogenic organism. As to treatment, a contagious ophthalmia must run its natural length, just as a case of scarlet fever does. The writer removes the lachrymal sac for suppuration. This operation is made easier by previously filling the sac with either paraffin or soft wax. As regards prophylaxis of acute conjunctivitis, it primarily concerns the other eye if this is still unaffected. The writer believes that in most instances bandages are productive of harm. Protection if necessary, is best afforded by a shade or by smoked glasses. As to fomentations, he employs them for only two purposes—to promote suppuration in the early stages of panophthalmitis, and to relieve the pain of rheumatic iritis.

A Case of Acute Endocarditis Due to the Micrococcus of Gonorrhea.—William Hunter records this case in which the condition was not discovered till post mortem, in a perfectly fresh cadaver. The patient was an unknown Chinese woman aged 38 years. The ante mortem history could not be learned. The aortic valve was found to be studded with delicate granulations, especially on its ventricular aspect. The process extended for a short distance over the neighboring endocardium. The granulations were pinhead in size, extremely soft, greyish-pink in color, and translucent. Microscopical preparations showed very many oval-shaped diplococci which did not retain the stain by Gram's method. A coccus morphologically identical with the gonococcus was obtained from the cultures on blood serum and blood agar. Results from examinations of the genital tract were negative, due to duration of the infection and to the presence of innumerable other microorganisms, the growth of which rapidly masks the true bacteriological nature of the lesions. Clinically and pathologically, however, the condition of the genital tract was diagnostic of the effects of gonorrhea. The gonococcus was not recovered from any other organ or tissue. This case offers an additional proof of a direct infection of the endocardium by the gonococcus. The writer believes that the gonococcus must be regarded as a microorganism capable, under certain conditions, of setting up widespread disease in the human body.

A Case Showing Spirilla in Blood Simulating Malarial Fever.—G. Browse cites this case which, if it had not been for the accidental discovery of spirilla during the search for the malarial parasite, would have been considered a case of malaria. The patient was a soldier, twenty-four years old. He was admitted to the hospital with a temperature of 104° F., pulse 129, and respirations 31. He complained of headache and the usual febrile symptoms. The spleen reached nearly to the umbilicus. On the fourth

day the temperature fell by crisis, and the symptoms rapidly abated. The temperature rose again on the thirteenth day to over 103°. On the fifteenth day it fell by crisis to normal, and from this date his recovery was uninterrupted. Blood examination revealed no malarial parasites, but spirilla were discovered in small numbers. The writer states that this case is exactly like many seen in the Punjab which are diagnosed as malarial.

Desquamation in Scarlet Fever.—D. Hamilton Kyle diagnosed a case coming under his care as one of scarlet fever. The patient was sent to the Fever Hospital. After ten days' detention, he was sent back to his home, as the superintendent did not consider it a case of scarlet fever. On the eleventh day, desquamation was in full swing; it was coarse and profuse. Although the writer could not trace the infection, he learned later that several cases of the disease had been reported by different practitioners to the authorities just before the one here described. At home, the boy mixed with the other children in the family, none of whom had the disease. During the fifth week, while the peeling of the hands and feet was not complete, he went back to a large board school without conveying the disease to any of his fellow students. There were no nasal or aural discharges in this case.

Berliner klinische Wochenschrift, March 6, 1905.

Treatment of Skin Diseases by Freezing.—Juliusberg reports excellent results in the treatment of various cutaneous disorders by means of freezing with carbonic acid gas. The apparatus used resembles that employed in connection with the freezing microtome except that the object holder is replaced by a nozzle with numerous perforations. The gas is allowed to act on the skin for thirty to sixty seconds, which causes the regions treated to remain frozen solid for one to two minutes. The method was applied in cases of acne, psoriasis, sycotic processes, leg ulcers, *x*-ray burns, cancroid, lupus and erythematous lupus. Psoriasis, lupus vulgaris and *x*-ray burns seemed to be unfavorably affected by the freezing, but in the other cases the results were fairly satisfactory. The most marked curative action was, however, shown in nine cases of erythematous lupus, of which all but one were most favorably influenced. The combination of cauterization by means of crude hydrochloric acid immediately after the freezing, according to the plan proposed by Dreuw, was also tried, and in seven cases of lupus vulgaris gave excellent results, but the author considers that its field of usefulness lies in the treatment of tuberculous affections of the skin that for one reason or another cannot be subjected to some sort of radiotherapy.

The Forensic Blood Tests.—Marx discusses this subject and points out the necessity for great experience and thoroughness of training in such work before it is allowable for a man to undertake a medicolegal blood case. The spectroscopic tests for hemoglobin and its derivatives are described in their various modifications as well as the Teichmann reaction, to which the author attaches great importance, saying that it should be tried in every case. Under some conditions, as for example, in the presence of rust, it becomes impossible to obtain a positive reaction. Another test which, however, is useful principally in the negative information it may give, is van Deen's guaiac test. A positive result with this is of less importance, since various substances other than blood may produce it. The microscopical identification of blood corpuscles is also of the greatest significance, but it is not often that it is possible to draw any conclusions from measurements intended to distinguish between human and animal blood. The newly developed precipitin tests have been found reliable when carried out by experienced workers, and it is not unlikely that the researches of Landsteiner and Richter may result in the perfection of a method by means of which isoagglutinins may be used to identify the individual person from whom the blood emanated.

Münchener medizinische Wochenschrift, March 7, 1905.

Gigli's Lateral Pubic Section.—Franqué, although he admits that even in hospital practice it may occasionally prove necessary to perform perforation of the living child, believes that in many cases the indications can be met with equal safety by making the lateral pubic section advocated by Gigli. The operation, followed by delivery either by the forceps or by version, does not require an appreciably longer time than perforation and extraction, and does not constitute a greater tax on the mother's strength. The author amends his former advocacy of the operation by stating that even in infected cases, with living children, pubic section may be and should be resorted to in suitable cases. Doederlein's recommendation to place the saw in position as a prophylactic measure, to be withdrawn unused if not actually needed, is a good one, and the author has devised a special ligature carrier by means of which the application of the saw is facilitated. Two cases are described in which the maneuver secured living children in the presence of apparently very serious complications.

The Morphology of Diphtheria and Pseudodiphtheria Bacilli.—Saul describes and illustrates by photographs differences in the morphological appearance of pure cultures of diphtheria and pseudodiphtheria bacilli. The cultures used as paradigms were from two cases, two months in age, and the author calls attention to differences in general shape of the bacteria, the branching, and the form of the plantlike growths resulting. The stem of the pseudodiphtheria plant is monilated, the segments decreasing in size according to their length and their distance from the parent stem, while the true bacillus shows a growth which is pear-shaped, gives off its branches unilaterally, and these divide into secondary twigs. The author also calls attention to the possibility of the grading of the true bacteria or bacterial masses with the protoplasmic granules in the cells of the higher plants and animals.

The Prevention of Puerperal Fever.—Doerfler concludes that the best means of prophylaxis against puerperal infection among the lower classes, lies in thorough education and supervision of the midwives. The following are some of the suggestions he makes in this regard. The genital tract is to be considered as theoretically aseptic, and as every unnecessary contact is a menace to the natural powers of resistance it must be rigidly avoided. Thorough asepsis on the part of the attendant is, therefore, required, and on beginning the care of a case, the genitals must be always disinfected. The use of rubber gloves by midwives is to be largely enforced, with appropriate penalties for non-observance. The use of non-sterile objects in connection with the parturient canal is to be made subject to legal penalty, as well as the administration of vaginal douches before or after the labor unless prescribed by, and carried out under the supervision of, a physician. Vaginal examinations from beginning to end of the pregnancy, are to be made only with rubber gloves, and the midwife should not leave the woman until two hours after the termination of the labor. The State should secure the payment of the legally established fees to the midwife, and the condition of midwives should be improved by the distribution of prizes for satisfactory work, and the establishment of governmental insurance, invalid, etc., systems. Every year the local circuit physician is to deliver a set of lectures on the principles of asepsis as applied to obstetrics.

Deutsche medizinische Wochenschrift, February 23, 1905.

Some Cases of Perforation of the Stomach and Duodenum.—Croce describes three cases which tend to show the effectiveness of the laparotomy in intestinal or gastric perforation, if the operation can be performed within twelve hours after the accident. The first was that of a gunshot wound of the stomach, inflicted with suicidal intent. The patient was operated on very soon afterward, and a perforation of the anterior and posterior wall of the stomach repaired by suture. The region of the injury was sponged off and drained, most of the incision being sutured. A prompt and uncomplicated recovery followed. The second patient was an old gentleman who for years had suffered from gastric ulcer. One morning on the way to his office, he suddenly experienced acute pain in the epigastrium, and as he had been warned by his physician of the possibility of this accident, he at once betook himself to a hospital. The abdomen was opened within two hours and was found full of stomach contents. The ulcer was sutured, the abdomen washed out and the wound partly closed, a drain being carried down to the gastric sutures. Recovery was uneventful. The third case was a doubtful one and did not come to operation until nearly twelve hours had elapsed. General symptoms of perforative peritonitis were present, and on opening the abdomen the source was seen to be a ruptured duodenal ulcer. The abdomen was full of purulent exudate and it required 30 liters of salt solution to cleanse it. Extensive iodoform gauze drains were inserted and the wound left open except for two silver wire sutures. In spite of pulmonary and other complications, the patient is now almost ready to be discharged cured.

Light Phenomena Produced by Rubbing Incandescent Electric Light Bulbs on the Human Skin.—Sommer describes a peculiar luminous appearance which is manifested by electric light bulbs disconnected from their circuit, if they are rubbed with the bare hand. Not all bulbs show the phenomenon, those that are new or have been but slightly used giving the best results, as the coating of carbon to be observed on old ones seems to interfere with the production of the luminosity. On rubbing such a bulb briskly against the forearm or the forehead, and suddenly lifting it from the skin, the bulb will become luminous. If the bulb is rubbed against one part and is then touched to another, as for example the cheek, light will be produced without further friction. The phenomenon may also be made to appear by breathing on a bulb that has been rubbed against the skin. The purely physical nature of the phenomenon is shown by the fact that friction with inanimate substances, such as woolen cloths, clothing, etc., will produce the same results. By using a fox brush as the

exciting agent, the author succeeded in producing images of opaque objects, such as coins, on a photographic plate.

Blaschko's Abortive Treatment of Gonorrhea.—Block warmly commends this method, which he says is reliable, though the lack of success attending other plans of abortive treatment has caused attempts of this sort to fall into discredit. Out of 215 patients, 44 proved suitable for the effort to cut short the infection to be made, and in sixty-four per cent. of these the result was satisfactory. Great care is necessary in selecting the cases, which must have but slight nonpurulent discharge without any urinary symptoms other than slight tickling. The gonococci should still be extracellular. Fresh three per cent. protargol solution is injected once daily for three days, and is retained five minutes at each session. If no reaction is produced, on the fourth day, four per cent., and on the fifth day, six per cent. solutions are used. On the seventh day the secretion is examined, if gonococci are still present the abortive treatment has failed, and one should revert to the ordinary milder plan; if none are found the patient should return several times more in order to be sure that the infection really has been cut short. A cure can be assured only if the urine is quite free from secretion or the threads are of catarrhal and not purulent nature.

French and Italian Journals.

Contagion of Trachoma.—Poulard communicates observations which he has recently made in relation to the contagion of trachoma. A father brought his seven-year-old daughter to the clinic for treatment. The child was afflicted with a chronic conjunctivitis without secretion. On turning back the upper eyelid the lesions of trachoma were distinctly seen. Both eyes were affected. The conjunctivitis was of more than a year's duration. The father's eyes had been affected for several years. Examination easily proved that the conjunctivitis in his case was exactly similar to that of the little girl—the same chronicity, the same slow evolution, the same localization, and the same kind of lesions. There were besides, cicatrices of the upper tarsal conjunctiva, and trachomatous lesions of the upper half of the cornea. There were four children and the mother at home. The writer made a visit to the house and discovered that they all had trachoma, even the youngest child who was only three months old. A neighbor and her child who often visited the family were found to have a distinct trachomatous conjunctivitis. The child was first attacked, then the mother. There was one washcloth only in use in the family, and this probably offered the method of transmission. This same cloth was used now and then on the neighbor's child, who was confided to the mother's care for the day. The writer has observed numerous cases of trachoma which have extended to all of the members of a family.—*Recueil d'Ophtalmologie,* February, 1905.

Syphilis and General Paralysis.—Apropos of the recent discusison in relation to syphilis and general paralysis, Joffroy offers the following conclusions: Syphilis is not the essential cause of general paralysis; general paralysis is not an affection of syphilitic nature; mercurial treatment is not prophylactic in general paralysis; mercurial treatment is not curative in general paralysis; mercurial treatment [illegible] without danger for general paralytics. *Gazette des Hôpitaux Civils et Militaires,* March 9, 1905.

Iliac and Pelvic Adenophlegmons Consecutive to Lymphangitis of the Leg.—Savariaud believes that the development of abscesses of the iliac fossa and lateral pelvic abscesses consecutive to lymphangitis of the leg, are quite frequent. Suppuration of the external or internal iliac ganglia is always preceded by inflammation or even by suppuration of the inguinal ganglia, which constitute the first stage of lymphangitic infection. The seat of retroparietal collections is sometimes in the iliac fossa, above the crural arch, and sometimes in the prevesical space. The development of the abscess is accompanied by frequency of micturition from irritation and compression of the bladder.—*La* [illegible]

Hemoptysis in Tuberculosis.—Hérard de Bessé describes the case of a man aged twenty-three, who had been tuberculous nearly all his life. Up to this time there had never been any serious hemoptysis. The vascular system was very sensitive, and the patient was subject to congestive attacks. One day, while at dinner, he was suddenly attacked with a hemorrhage. These attacks continued almost daily, often occurring several times in the twenty-four hours. Each time there was from 50 to 150 grammes of bloody expectoration. The heart was normal, but the pulse was rapid, generally more than 100 beats a minute. Arterial hypotension was noticeable. Many remedies were tried—opiates, ipecac, hydrastis canadensis, ergotine, calcium chloride, sodium bromide, quinine, digitalis, sulphate of soda, benzoate of soda, aconite, and so on. Various measures, too, such as the sitting position, ligature of the legs, and an icebag over the region from which the hemorrhage was thought to come, all were tried. The chloride of calcium seemed to have scarcely any influence on the coagulability of the blood, although it was faithfully given throughout nearly all of the illness. The action of the gelatine was entirely different. After a hypodermic injection of 10 c.c. of a solution of gelatine, without sodium chloride, the hemoptysis was arrested. The next day, the sputum was decidedly solidified. The icebag had been placed over the hemorrhagic focus at the same time that the injection was given. Forty-eight hours later the patient was able to be transported in a wagon to a sanatorium, the journey taking two hours. For some time the bleeding did not recur, and cyanosis disappeared. But a new attack of hemoptysis occurred, and the patient died. The writer believes that the drug of choice to be used in these cases is ipecac in doses that nauseate. If this drug is badly borne and the desired results are not obtained with it, then one should have recourse to gelatine, which is harmless after being sterilized, and which, better than anything else, will favor the formation of a clot. The patient should keep quiet in order not to disturb the clot. If these measures do not succeed, he is convinced that nothing else will be of much use. He thinks that it is always to be regretted when ipecac and gelatinized serum are kept as a last resource.—*Journal des Praticiens,* March 11, 1905.

Muscular Syphilide.—Giambattista Tacelli tells us that syphilitic affections of the muscles are not uncommon, beginning in the secondary period with the muscular pains at night resembling rheumatism, and increasing in frequency during the tertiary period, when we have asthenia of the muscles from lack of nutrition, contractures myositis, tremor, sclerosis of the muscles and gummata in the muscles, going on the degeneration and suppuration. During his studies he has met with two interesting cases of muscular lesions in patients that were undoubtedly syphilitic. The first was a case of contracture of the biceps muscle, placing the elbow in a state of flexion. There was no pain on pressure, but extreme pain on any attempt to move the muscle actively or passively. The condition came on suddenly; there was loss of galvanic excitability, and the muscular tension disappeared under chloroform. There was no alteration of the articular apparatus or tendons, as in reflex contracture; no tenderness, as in myalgia, and no evidence of nervous origin. The disturbance was purely functional. There were skin lesions present at the same time. The other case was one of gummatous infiltration of the sternocleidomastoid, with diffusion into the surrounding connective tissue, and ulceration of the superimposed skin. Gummous myositis may be localized in any muscle, but the most frequent location is the one in this case. It occurs frequently in the tongue. The functional disturbances are always small.—*Giornale Internazionale delle Scienze Mediche,* February 28, 1905.
